process or group of processes. On the down side, required sample volumes are usually greater than for other PAC techniques, and samples are likely to require preconditioning such as dilution prior to delivery to the titration vessel. Most systems require a higher than average level of maintenance due to reagent usage and the relatively large number of moving parts. Titrators also create waste from the titrated sample and wash solutions. These characteristics may make titrators well suited to at-line applications where an operator can take full advantage of their flexibility for troubleshooting or support of multiple processes, and their limitations are less of an imposition. Nevertheless, on-line titrators are widely used for a variety of measurements in industry. Figure 5 shows an on-line autotitrator installation for measuring sulfide in dye and pigment processing.

Flow injection analysis (FIA) utilizes small volume streams flowing at precisely controlled rates to accomplish the volumetric measurements required for wet chemical analysis. By transforming volumetric control in a batch environment to rate/time control in a flowing environment, FIA allows the use of smaller samples and reagent volumes than are used in traditional titration, and the analyzer system may be mechanically simpler than a titrator. These characteristics usually result in lower operational and maintenance requirements, making these systems good candidates for on-line applications or for at-line applications where the operator has limited familiarity with analytical methods. Figure 6 shows one such at-line application for measuring dissolved metals in the processing tanks of a metal finishing plant. These benefits come at the expense of flexibility, however. FIA method development is more time-consuming than normal titration, and the resulting methods usually require tailored analyzer hardware, making them less amenable to change in response to changing process requirements.

Titrators and batch mode FIA methods operate on discrete samples from the process, so they do not provide continuous, real-time data on the process. When used in continuous flow mode, FIA can provide continuous data with only a slight time delay in the results. Neither technique can be considered in-line. Analysis times depend on the chemistry, but for an automated on-line instrument the time required for a complete cycle of sampling, analysis, and purging to waste is typically in the range of 5–15 min. For an at-line system the analysis times are similar to those for on-line, but the manual sampling and sample preparation times may be considerably longer. At-line system throughput can be increased through the use of standard laboratory autosamplers, but the delay from the time of sampling to the delivery of the analytical results will still be considerably longer than for an on-line system. More detailed information about the use of titration and flow injection methods can be found in the

3.2 Chromatographic Techniques

Chromatographic techniques have been the most widely applied of all PAC techniques. As in all chromatography, a very small volume of sample is injected into a carrier stream and passed through a column of selectively adsorbing material where the sample components are retained to varying degrees and then detected individually as they exit the column. The resulting data provide an indication of the relative concentrations of the detectable components in the process. Contaminants or unwanted components may be detected when present in sufficient concentration, but these techniques are generally not used for trace analysis.

All types of chromatography have been used in PAC. GC is the typical choice for gaseous and volatile organic liquid samples, normal and reversed phase liquid chromatography (LC) for nonvolatile organics, size exclusion chromatography for polymers, ion chromatography (IC) for ionic species in water, and supercritical fluid chromatography (SFC) for large, nonvolatile, or heat-sensitive molecules. Since chromatography, like titration, involves processing discrete samples outside of the process, it is not compatible with an in-line approach and does not provide continuous data. It can only be used where samples can be taken from the process without significant degradation.

GC is the most widely used on-line process analysis technique in industry. Much of its popularity in the petrochemical industry is due to the fact that it is a standard laboratory method for determining chain length distribution (carbon number), and the value of making this measurement on-line is high. A similar application is shown in Figure 7 where a process gas chromatograph is being used to determine the heating value of natural gas on a production platform.

GC provides analysis times typically in the 2–15-min range and a rapid and straightforward sampling interface to the process (especially for gaseous process streams), but it also has its problems. Maintenance issues such as column aging, shifting retention times, injection valve life, carrier gas consumption, and safety issues for flame ionization or electron capture detectors, may make GC a less desirable option if spectroscopic or sensor-based techniques are available.

LC, both normal and reversed-phase, is less widely applied in PAC than GC. LC has most of the same maintenance and safety problems that are associated with GC, only to a greater degree. It has the further disadvantages of relatively long analysis times (typically 10–30 min), less separating power, and higher equipment and operating costs owing to the need for solvents, precision pumps and high-pressure operation. Nevertheless, the pharmaceutical industry, which uses LC as its workhorse technique in the laboratory, is looking increasingly at process LC. Developments in chemometric treatment of LC data are enabling shorter analysis times by providing analytical resolution with far less than perfect peak resolution. These data treatments can be applied to all types of chromatography.

IC and SFC are more specialized than LC and less commonly used. These techniques have analysis times similar to LC, but are less stable in automatic operation and have higher operating and maintenance costs. SFC is sometimes substituted for LC, especially where supercritical carbon dioxide can be used as a safe (nonflammable) mobile phase. In most cases, though, some other analytical method can be found which will be more reliable and cost less. A later article in this section (Chromatography in Process Analysis) provides further information on application of these techniques.

3.3 Spectroscopic Techniques

While GC has been the most widely used PAC technique to date, spectroscopic techniques are exhibiting a faster rate of growth in usage. Microwave, infrared (IR), NIR, Raman, UV/visible, and X-ray spectroscopy offer...
a host of possible methods for process analysis. Four other articles in this section specifically address the use of IR (Infrared Spectroscopy in Process Analysis), NIR (Near-infrared Spectroscopy in Process Analysis), Raman (Raman Spectroscopy in Process Analysis), and UV/visible techniques (Ultraviolet/Visible Spectroscopy in Process Analyses). General advantages of this group of techniques include measurements which are in-line, continuous in real time, and noninvasive (as defined in section 2). The measurements may also offer a high degree of specificity for the analytes of interest, the ability to determine multiple analytes with a single spectrum, and, for simple cases, the equipment may be inexpensive. While all of these advantages are possible in general, they are usually not all true for any specific application.

Spectroscopic techniques can be used for at-line and on-line applications by measuring process samples or a side stream. However, one of the major advantages of these techniques is their ability to make direct process measurements in-line, usually producing a continuous stream of data in real time. If the process is enclosed, this is usually done using windows in pipes or vessels through which the spectrum of interest can freely pass, or using waveguides or fiber-optic probes to transmit radiation into and out of the process stream. Figure 8 shows a NIR fiber-optic system used for monitoring the process in a reactor vessel. If the process is in the open air such as for films, webs, or solid materials on a conveyor, windows or probes may not be needed. Figure 9 illustrates one such application, an open-air NIR measurement of moisture for a papermaking process.
As with laboratory-based spectroscopy, the ability of a spectroscopic PAC technique to monitor an analyte of interest depends on that analyte having some unique feature or combination of features in the spectral region being measured. This is the primary requirement for the use of these techniques. If an analyte has a single unique and strong spectral feature, it may be monitored with rapid simple methods and inexpensive equipment, such as the continuous measurement of a single or pair of wavelengths using a colorimeter or filter photometer. For multiple analytes, analytes with less pronounced spectral features, or process streams with components which have interfering spectral features, more capable instruments are needed to acquire data from many wavelengths, and more sophisticated data analysis techniques such as chemometrics may be required to extract useful information. Unfortunately, the spectral complexity of many process streams is beyond our current capability to unravel, even with the best equipment and data analysis methods.

When data from multiple wavelengths or the entire spectrum must be collected and processed to produce the desired result, the measurements will be discrete instead of continuous, but the frequency can still be quite rapid, usually in the range of several times per second to several times per minute. When analyte concentrations are low or there is spectral interference, signal averaging may be useful to enhance weak signals which are near the noise threshold. Using signal averaging will also reduce the frequency of the resultant measurements.

Another requirement of spectroscopic techniques is that the probing radiation should penetrate into the process stream and return a spectral signal. A process matrix which is opaque or nearly opaque to the measuring
radiation will return a very weak spectral signal which represents only the material in immediate contact with, or very near, the sampling window or probe. If mixing is not excellent in this region, the spectral signal will not be representative of the process stream. Fouling of the sampling windows or probes can also restrict penetration into the process stream, and result in no measurement or a measurement biased by the composition of the fouling material.

The complexity of spectroscopic PAC applications varies widely, and the cost varies widely, as well. Spectroscopic techniques are more stable and mechanically reliable than titrators or chromatographs, and they do not require consumables such as reagents or carrier fluids. The simple example of the inexpensive colorimeter represents the low end of the cost scale. The initial cost of such an instrument is relatively low, and the maintenance cost will also be low if the process is moderately clean and the operating environment not too demanding. In the middle range will be systems such as the moisture meter in Figure 9 used to scan the web of a papermaking machine. The instrument and installation are more complicated, and the operating conditions it must endure are more demanding. At the high end of the range will be systems requiring full spectrum spectrometers with difficult interfaces to the process, advanced data analysis capabilities, and which require protection from severe environments. Not only will the initial costs of these systems be high, they will also require more maintenance from more highly skilled operators and technicians. Building and maintaining the multivariate models needed for these instruments is time-consuming and frequently requires the efforts of a trained chemist, chemometrician, or equivalent skilled personnel.

3.4 Sensor-based Techniques

Chemical sensor-based measurements might be considered the ideal method for implementing PAC. They have the potential to provide instantaneous and continuous chemical information about what is happening inside a process stream at very low cost. This is the kind of information that process engineers need most to operate a process at optimum conditions. Sensors are often used for in-line measurements such as the application shown in Figure 10 where the humidity of drying air is monitored using a polymer film capacitance sensor. They can also be used for on-line measurement of a side stream, or at-line on an extracted sample. Many other instrument types such as titrators, flow injection analyzers, and chromatographs use chemical sensors as detectors in making their measurements.

We can define a chemical sensor as a device which when exposed to a process stream delivers a signal which provides information about the chemical composition of the stream. The range of chemical sensors from which we can select is very broad, and new sensor development continues to be a significant area of PAC research. We will not attempt to provide extensive information about sensor types in this article. Instead we refer you to the further information at the end of the article (especially I, II and V) for references on sensor performance and application information and sources of equipment.

The ideal sensor should provide a continuous signal which is highly selective for the analyte of interest and sensitive enough to pick up the smallest meaningful change in the analyte instantly. It should also be very small, impervious to attack by any components or contaminants of the process stream, unaffected by the process temperature or pressure, physically robust, highly reliable, and cheap. While there may not be any truly ideal sensors, there are some which come close. Ion-specific electrodes, humidity, pH, and oxidation–reduction potential probes and sensors are good examples which have seen broad application and are nearly ideal for some processes. Advances in sensor technology are occurring almost daily. Inexpensive and even disposable sensors under development for the medical field may soon become available for PAC, too.

As a closing comment on sensor-based techniques, we note that there are technologies now in use and being developed which tend to blur the distinctions between sensors and other categories of PAC techniques. By our definition a fiber-optic probe for a spectrometer such as the one shown in Figure 8 might be considered to be a sensor because it returns a signal containing chemical information when exposed to a process stream. New devices and technology are putting techniques like
spectroscopy into a small package with characteristics similar to a chemical sensor. Fiber-optic pH probes are an example. Likewise, when microminiaturization makes it possible to put chromatography or FIA on a silicon chip, these techniques will be freed from some of their limitations and will be deployable as sensors.

### 3.5 Other Techniques

While many techniques used for PAC fit into the four categories already described, there are a variety of measurement techniques which do not. We cannot enumerate and describe them all, but a few examples may be useful. One such technique is mass spectrometry (MS), which ionizes a gaseous sample stream and then uses magnetic and electric fields to separate the ionic species by charge-to-mass ratio so that they can be quantified individually. MS is used primarily for gaseous processes, where it can deliver continuous measurement data in an on-line configuration. Because of the requirement of a gas phase sample stream, MS has not been used broadly in PAC. There is development work underway to extend its application to a broader range of samples. An article Mass Spectrometry in Process Analysis later in this section provides further information on the use of this technique.

Nuclear magnetic resonance spectroscopy is another technique which has been little used in process analysis to date because of the requirement to place the sample within a strong magnetic field. But developments with this technique have also made it the subject of increasing interest for process application. Details on these developments are covered in the article Nuclear Magnetic Resonance and Magnetic Resonance Imaging for Process Analysis later in this section.

The various atomic emission and absorption spectrometry techniques do not share the application characteristics of the molecular absorption spectroscopy techniques described earlier in this article. The emission techniques decompose and excite a sample using high levels of energy, usually in a flame or plasma torch, and then detect the radiation emitted by atomic transitions. Atomic absorption also decomposes the sample, but then detects the atomic transitions by measuring radiation absorbed by the sample. All of these techniques are used for identifying and quantifying elements, and will not provide complete analytical information when used on mixtures of compounds which contain the same elements. They are sensitive to low concentrations of metals, and are often used for wastewater monitoring, sometimes in an on-line mode. They are less useful for on-line monitoring of more complex mixtures owing to the interpretation or additional information required to deconvolute interfering species. In addition, these instruments require consumables such as acetylene, hydrogen, or argon to sustain the flame or plasma used to atomize and or excite the sample.

X-ray fluorescence spectrometry is similar to atomic emission spectrometry in that X-ray energy excites a sample and the resultant radiation emitted by fluorescence is measured. However, X-ray fluorescence is more like absorption spectroscopy because no external support gases are needed. X-ray fluorescence can be a continuous, real-time in- or on-line measurement technique. Its primary difficulties are associated with the use and limitations of the X-ray radiation. This technique finds its use in process analysis for a relatively small number of specific applications, typically in the mineral processing industries and certain web-coating processes.

Another group of techniques uses radiofrequency or microwave radiation to measure dielectric properties which infer chemical information. These methods are on the fringe of what might be considered analytical spectroscopy. Most often used for moisture determination in solids, these techniques can provide continuous data in either in-line or on-line configurations. Many commercially available models are designed for production facility installation, with features like hardened enclosures and built-in capabilities for calibration, fault determination, and self-diagnosis.

### 3.6 Technique Selection

While the categories just described do have functional value in considering the application of techniques to process analysis, we recognize that there are other criteria for categorization which could have been used. The purpose of the categories is only to aid us in a high level selection of which techniques are reasonable candidates for use in a particular application and which are not. Regardless of how we categorize the techniques, or the category from which the candidates come, the criteria we use for the final selection from among the candidates remains the same – performance in the process. The performance factors which must be considered include at least the following:

- selectivity
- sensitivity
- response time
- resistance to attack by chemicals in the process stream
- temperature and pressure sensitivity
- resistance to physical damage
- compatibility with operating environment
- reliability and reproducibility
- stability and calibration frequency
- aging characteristics
- self-diagnostic capability
- initial cost
- replacement cost
- maintenance costs
- consumable costs.

Other factors may be added to this list to account for the special needs of the process or operating environment. By prioritizing these factors and evaluating each technique by its performance in each area, it is usually possible to narrow the range of candidate techniques to a few, and possibly one. Occasionally a PAC technique can be identified which is a perfect fit to the needs of a process. Usually, though, the selection will involve some performance trade-offs. Knowing the relative value of the different performance factors is the key to evaluating these compromises. It must be stressed that detailed knowledge of the process requirements and operating environment is a prerequisite to prioritizing the factors and making the selection. Adequately defining the problem and gathering information about the process are the first two steps in the flow chart in Figure 1. They are critical to success, and they must be done first or time and money will be wasted.

3.7 Summary

It is obvious that we cannot do justice here to the full scope of options available in PAC techniques. We must refer you to the references in this Encyclopedia, and to the marketplace to discover what is available. As we have noted before, PAC technology is a rapidly developing field. In the lists of further information we have made an effort to identify both classic works, which provide a foundation for conceptual understanding, and materials and networking sources which will be updated regularly to reflect the current state-of-the-art.

4 SAMPLING AND SAMPLING PREPARATION ISSUES

One of the biggest issues in PAC is obtaining a representative sample. This is important for the obvious reason that we want to know what is going on in the process and not be misled by stream inhomogeneity, and because calibration of the process instrument and correlation with the laboratory measurement require “true” samples. Sampling systems are also needed for some on-line measurements to “condition” the sample prior to analysis. As an example, consider the situation in which the moisture on a conveyor belt of grain is being measured using a NIR filter photometer. The photometer must be calibrated against the laboratory measurement, which is a loss-on-drying measurement. The conveyor belt is 4 feet wide (122 cm) and the product depth is 5 inches (approximately 13 cm). Good sampling procedures require that the position across the belt, depth, and timing of the grab sample taken to the laboratory be considered. Obviously, the sampling position must match the position which the NIR light is measuring. If the product is “turned over” to expose grain from beneath the surface, that must be sampled. The grab sample should also match the time constant of the NIR measurement. In a liquid measurement such as hydrocarbon distribution by GC, the issues are similar. The stream to the GC must be continuously flowing and the timing of manual sampling must be matched to the GC injection. (What is the process flow rate?) If the instrument is 5 m away from the sample valve, the sample must be drawn taking the lag time into account. If the process is at steady-state (the ideal), this issue is less critical.

Even if sampling issues are carefully considered, the laboratory results may not agree very well with the process instrument results. Most often this is because the two methods are not identical. Even a simple pH measurement may not agree with the laboratory measurement because of temperature differences, dilution differences, and so on. In the grain example, the differences between the laboratory drying method and the process NIR method must be understood. The laboratory method may be a total moisture method, while the process NIR may be measuring only the unbound water. In the sugar example from section 2, this was the prime reason for selection of in-line refractive index for the measurement – it was the same method as used in the laboratory. It is important that operating personnel understand that two methods may not give identical values. In addition, many samples undergo changes between sampling the process stream and analysis in the laboratory. Samples may cool down or warm up, water or solvents may evaporate, reactions may begin or continue, the sample may be exposed to air, and so on. For some processes, samples must be taken through special sampling ports to maintain process sterility (e.g. fermentation). Samples drawn from such processes must also be protected from contamination, lest microorganisms change the sample. Any change in the sample, prior to its analysis in the laboratory, can lead to disagreement between the result from the process instrument and the laboratory result. Such disagreement will have deleterious effects on instrument calibration and on operator confidence in the process result.

In some situations it is not possible to match the laboratory and process techniques or sampling procedure so that the results of the two approaches are identical. For process control, this is not necessarily a critical issue, provided that the operating personnel understand it. In this situation, the process measurement still “tracks”
the process and its results correlate to the laboratory measurements. The process operator or control system can still follow slow process changes and upsets and adjust accordingly. With sufficient data, the process instrument output may eventually be adjusted – perhaps at the control room display – so that the results match the laboratory. The important thing to remember is that people understand that this was done and why.

It is beyond the scope of this introductory article to delve into the details of sampling systems; that is left for a later article in this section, Sampling and Sample Preparation in Process Analysis. However, there are several key points the reader should think about:

1. Obtaining a representative sample of a varying process stream is not trivial, whether the sample is intended for analysis in the laboratory or PAC. In some cases a sample removed from the process changes before it can be analyzed in the laboratory. Some examples include thin materials which dry extremely rapidly, solvents evaporating from the sample as they are captured, reactions which are not quenched adequately, and so on. In these instances, it may be easier to bring the analysis to the process than to attempt to improve the sampling procedure for a laboratory sample.

2. A sampling system for PAC has five basic functions:
   - to take representative samples of the flowing system
   - to transport samples to the analyzer
   - to condition samples as needed (filtering, adjusting temperature, pressure, etc.)
   - to handle switching between sample streams, including a calibration stream or tank
   - to return samples to the process or waste.

3. The definition of the term “representative sample” depends on the process, analyte of interest, and the technique being used. Therefore, the sampling procedure must be appropriate for the specific PAC application. Representative does not necessarily mean that the sample is identical to the process stream. For example, it may be necessary to filter a sample to remove particulates which would contaminate a GC system. If the concentration of the analyte of interest is unaffected by the filtration, the sample is representative in the analyte, but technically it is not identical to the original.

4. As in the real-estate business, the critical factor for sampling is location. The sampling point must provide a representative sample for the analyzer in a timely manner so that unnecessary delay is not added. Therefore, not only is the location important, so also is the flow rate of a sample line. It may be necessary to install a high speed pump to deliver the sample stream to the analyzer.

The variety of functions which a sampling system must perform often causes these systems to be complex. Figure 11 shows one example of a system used to sample and filter four different petroleum process streams for

![Figure 11](image-url)
delivery to an on-line analyzer. It should be evident that
care must be taken in the design and construction of
such a sampling system to prevent it from becoming a
maintenance headache or the source of frequent overall
system failure.

5 DATA TREATMENT

Data treatment begins with data. In its simplest form
the data consist of a single value, at a given time,
transmitted as an analog, most commonly a 4–20 mA
signal. (Generally, an at-line instrument does not transmit
its data at all, but has its own display or computer
with it. This discussion is intended for in-line and on-
line measurements.) In the case of a single value being
transmitted as an analog signal, what data treatment issues
must be considered? First, the instrument itself must be
properly calibrated. In addition, the analog output must
be spanned properly, to maximize signal resolution. For
example, if the pH of a wastewater stream which is
typically at ~6.0 is being monitored, the meter must be
calibrated with buffers, say 4 and 7. In addition, the output
of the instrument should be set so that a pH of 4 gives 4 mA
output and pH 8 gives an output of 20 mA. This provides
a reasonable range for the application, with the target
or typical value at 50% of the range. If the instrument
output ranged from 1 to 14 pH units, resolution would
be significantly poorer. Similarly, if the output is going to
a process control system (programmable logic controller,
PLC, or distributed control system), the input of the
control system also must be set properly. In addition,
the output and the input should be calibrated for correct
current reading.

A more complex situation occurs when the instru-
ment provides more than one signal. In the pH example,
perhaps the instrument can transmit both pH and tem-
perature. Now both 4–20 mA signals must be calibrated
and correctly spanned.

The most complex situation occurs when an instru-
ment makes multiple measurements or uses its own computer
to calculate a value from the raw data. Gas chromatographs
and NIR spectrometers are examples of these more
complex cases. The gas chromatograph provides data
on multiple compounds in the sample stream. It must
extract this from the chromatogram peak areas, apply
appropriate calibration functions, and then move the data
to the control system in a usable form. In doing all this, we
must be sure that the instrument correctly recognizes each
peak (compound) and that the quantitation is correct. A
system must be designed in which calibration standards
can be analyzed. In the example of the NIR instrument, it
acquires a spectrum of the sample and converts that
spectrum to quantitative information on the sample.
This could be from several wavelengths or the whole
spectrum. If a chemometric model is used to obtain the
concentration data, a lot of effort probably went into
developing and validating the calibration model. If it is
intended to use the same measurement in other locations
of the plant or another plant, much effort can be saved
by transferring the calibration from one instrument to
another. Calibration transfer is one of the biggest areas of
research today and should be investigated carefully before
proceeding. Calibration model building, and calibration
transfer, and other information on the use of chemometric
techniques are addressed in a later article in this section
on Chemometric Methods in Process Analysis.

As discussed in section 4, agreement between the
laboratory and process analytical results may not always
be perfect. In general, the laboratory result is assumed to
be the “correct” one. The process instrument is used to
monitor and control the process and in many cases need
not be “accurate”. It is more important for a process
measurement to be precise and reliable. Of course, in
some cases, PAC data may be more accurate because of
the sampling issues described in section 4 (samples which
change en route to the laboratory, etc.). In this situation,
however, how do we know what accuracy is? If the
laboratory samples change, but the laboratory method is
the “accepted” way to make the measurement, how can it
be demonstrated that the PAC measurement is accurate?

Operator confidence in PAC instruments comes when
the instruments are up and running and not being
repaired or calibrated every few days or weeks. It comes
from quality results, which are not varying too much
(short term) or drifting (long term). Put another way,
the PAC instrument needs to have sufficient precision
(repeatability, reproducibility) for the data to be useful
to the process engineer, operator, and control system.
The exact amount of short-term variation (noise) or long-term
variation (drift) any process can allow in its instruments,
while still operating efficiently, depends on that process
and its target value. The target is normally chosen for
quality, safety, or cost reasons, so there is no blanket
rule for what level of precision a PAC measurement
should have. In some instances, it is acceptable for the
measurement to be ±10%, in others it must be 25 times
better (lower).

An increasingly important development in PAC is
instrument fault detection. More and more instruments
now have the ability to diagnose problems within the
instrument and alert the operator. This can prevent faulty
data from being used. For example, some pH analyzers
now monitor the impedance of the glass electrode and
signal an alarm if it has reached the point of poor
pH measurement. In addition, chemometric techniques
are being developed to do much the same thing for
multiple measurements on the process. The data from many measurements are examined and “odd” results are flagged. In many cases, a faulty result may be traced to an instrument problem; in others, the software can “validate” the questionable data and verify that a real, but unusual, process change has occurred. These two developments should become quite significant as PAC moves into the 21st century.

6 BUSINESS AND OWNERSHIP ISSUES

6.1 Business Case
As mentioned at the beginning of this article, industry uses PAC to gain financial advantages. If an application of PAC is to be successful, there must be a business case which solidly justifies it. All business justifications are ultimately based on profit generation, but not all arise directly from the economics of the process being measured. Identification and evaluation of the benefits and costs of the PAC application are necessary to build this justification.

Improvement in process control is the driver for most economic benefits from PAC. The costs of providing measurement tools to improve process control must be balanced by the benefits of what that control can deliver. Increased yields, increased throughput, improved quality, reduced raw material costs, and reduced waste costs are all examples of recurring benefits from improved control. These benefits derive directly from the process economics and are usually straightforward to assess.

Avoiding the costs of process excursions and upsets is another benefit of improved process control. The costs avoided may not be limited to the value of time, material, and labor which is lost when a process goes out of control, but may also involve regulatory fines and the cost of injury or chemical exposure of the workforce. The economic value of cost avoidance is more difficult to quantify than recurring cost reductions, but it is often a critical element in the business case.

Benefits which are further removed from the process economics can also provide justification for PAC applications. Strategic or competitive advantage in the marketplace may be derived from process changes which can only be achieved through the use of PAC. Safety or regulatory requirements may also dictate the application of PAC measurements to monitor emissions, or they may render a process noncompliant without improved process control. When these high level drivers from the business environment are at work the direct impact of PAC on the process economics may become a secondary consideration in the business case. The process economics should nevertheless be fully defined because they are an important element in designing the PAC application and in optimizing the result.

Another important indirect benefit of PAC is the insight into the process which is gained through the new information it provides. It is rare for a new PAC installation not to teach the process engineer or chemist something new. For this reason, PAC should be a key feature of all pilot plants and small-scale facilities, especially where process development and scale-up are involved.

The other half of the business case considers the costs of making the improvement. These costs should be considered in two categories: initial and recurring.

6.2 Initial Costs
It is fortunate that process improvement projects like those associated with implementing PAC technology can be divided into phases. These phases provide a convenient means of delineating and controlling the costs of a project, and of redirecting or halting projects which are not on track to meet the desired objectives. The following is an example of a high level outline which can be used to identify the initial costs of a PAC project.

- Preliminary phase
  1. Determination of process need and business case
  2. Evaluation or development of PAC techniques
  3. Design of PAC system

- Installation phase
  1. Capital acquisition
     (a) instruments and controllers
     (b) sampling system
     (c) data collection, communication, and archiving system
     (d) environmental protection for system components
  2. Modifications to process equipment
  3. Installation of utilities and consumables

- Implementation phase
  1. Training of workforce
     (a) operators
     (b) maintenance technicians
  2. Transition period
     (a) working the bugs out
     (b) learning curve
     (c) acceptance by workforce
Such a project outline (called a work breakdown structure, or WBS, in project management terminology) is the best tool for estimating and accumulating the labor and nonlabor costs and the time period associated with any project. The example of WBS shown here would be adequate only for a very simple project. Most projects will require more detailed levels in the outline to identify clearly all sources of project costs and facilitate accurate estimates of what each cost will be.

6.3 Recurring Costs

It is also convenient to break down recurring costs into categories so that they can be more easily estimated and accumulated. The following list contains typical items which should be considered.

- Scheduled maintenance
  - Consumables
  - Calibration
  - Cleaning
  - Replacement of wearing parts
- Maintaining training and expertise in workforce
  - Operators
  - Maintenance technicians
- Unscheduled maintenance
  - Warranty or repair costs
  - Future upgrade or replacement

The labor and nonlabor costs associated with these items, together with their expected frequency, will provide an annual estimate for the recurring costs of a PAC application. The unscheduled maintenance items are perhaps the most difficult to estimate on an annual basis. The annual cost of instrument repairs can be based on the cost of a service contract if one is offered by the manufacturer, although if high skill levels are available in the local workforce this may be an overestimate. An annual replacement cost may be estimated by averaging the cost of a new instrument over its expected lifetime.

6.4 Ownership

A critical business factor which determines the success or failure of a PAC application is that of ownership. In discussing and planning for the ownership of a PAC system, there are two distinct roles to consider: the role of the champion and the role of the vested owner. Like the other business issues already discussed, these roles are not unique to PAC. They can be universally applied to any project in business.

The champion’s role is to act as an agent of change in the business system. This person or persons should have a position which is respected by, and has influence on, both the business decision makers and the people who will implement the project. The role consists of convincing the decision makers of the value of the project, of identifying and enlisting a person as the vested owner, and of overcoming the inevitable resistance to change which may come from any of the parties involved in, or affected by, the project. If the business case is solid, the task of convincing decision makers should be simple. Most of them will recognize a dollar when they see one. However, if the business case is a little more tenuous, the decision makers must rely on their trust of the champion’s judgement.

Identifying a vested owner for the completed PAC system is another task which is often done by the champion. The champion and the vested owner may be one and the same person. The vested owner of the PAC application has the role of continuing day-to-day support and maintenance of the system, and planning for future replacements and upgrades of the equipment and software. This person should be vested in the benefits from the system as well as sustaining the costs. If this is not the case, the risk is high that the system will not be adequately maintained in the long term. In some manufacturing organizations, the management structure is not set up to allow direct control of system maintenance by the process owner who benefits most from the system. With costs and benefits assigned separately to two different people, probably in two different organizations, conflicts in priorities often develop. This situation should be avoided whenever possible, or mitigated through the influence of higher level managers who can maintain adequate priority for maintenance and planning for the future.

The most challenging aspect of the champion’s role is overcoming resistance to change. The vested owner also often participates in this task. Resistance to change can come from many directions. The workforce or a union may perceive the change to be a threat to job security, and this may be an accurate perception. Local management may resist because of memories of previous difficulties with PAC or other measurement systems not associated with chemical analysis. Technicians or operators may resist because the change was not their idea, or perhaps because they have something different in mind. Change often seems to breed resistance just because it is change. The reasons can be endless, and all of them represent a risk to the success of the project. The champion and vested owner must do everything possible to reduce the risk by winning people over with reasoning, accommodation, and leadership, and then make whatever plans are possible to mitigate the effects of any remaining resistance.
All the business and ownership issues dealt with here are common to successful projects in virtually any business environment. There are many excellent books, periodicals, and training materials available on these subjects, a few of which are given as references in the further information section.

FURTHER INFORMATION

There are many sources of information on PAC, including the other sections of this Encyclopedia. Some valuable books and journals are listed below in sections I and II. Section III lists some of the many conferences sponsored by analytical chemistry and engineering societies which have sessions devoted to process measurements. Short courses on the subject are also available, some of which are listed in section IV. Guides for locating instrument manufacturers are shown in section V, and the manufacturers themselves can be quite helpful. Research consortia such as the Center for Process Analytical Chemistry (University of Washington, Seattle) can also provide a wealth of knowledge. Finally, section VI lists a few of the many resources available for improving the probability of a successful implementation of PAC by planning and managing the project well.

1 INTRODUCTION

1.1 What is Chemometrics?

The definition of “chemometrics” varies greatly, often depending upon the context of the definition. Wise and Kowalski\(^3\) and Massart et al.\(^4\) place emphasis on the “chemo” root and classify chemometrics as a subdiscipline of chemistry that employs mathematical and statistical techniques to analyze chemical systems. Wold stresses that the impact of chemometrics is in problem solving and not data analysis: chemometricians “must remain chemists and adopt statistics to chemistry instead of vice versa”.\(^5\) Booksh and Kowalski\(^6\) and Brown\(^7\) have placed more emphasis on the “metrics” root and extraction of chemically relevant information from a series of complex chemically oriented observations. To this end, this article addresses a wide array of chemometric tools that are applicable to industrial process analysis. The three main sections present statistical and mathematical tools in the context of univariate, multivariate, and multiway analyses. Each of the three sections discusses the benefits and limitations of qualitative analysis, quantitative analysis, and process monitoring with the class of data in question. Additional sections address the appropriate pretreatment of collected data to aid in efficient analysis and validation of the derived chemometric models. In these sections methods for background correction and instrument standardization are discussed.

1.2 Roles of Chemometrics

Recognizing the constraints on space, the focus of this article concentrates primarily on established analytical methods that have been demonstrated to be useful in multiple applications. Section 1 provides the context and rationale for chemometric analysis. Descriptions of the chemometric methods are divided by the complexity of the data being analyzed. Section 2 addresses the techniques available to univariate data. Section 3 addresses qualitative and quantitative analysis with multivariate data. Section 4 describes the methods appropriate for multiway data. Sections 5 and 6 discuss preprocessing of data before analysis and validation of the derived models after analysis, respectively. These references are not comprehensive but are intended to give a representative cross-section of the authors and applications found in the literature. More information on current applications of chemometrics in process analysis chemistry can be found in the “Application Reviews” published bi-annually in Analytical Chemistry.\(^1,2\)

Chemometrics may be loosely defined as the development and application of mathematical and statistical techniques to aid in the analysis of chemical data. The goal of chemometrics is to guide the chemist in the optimum

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
defined chemometrics more as information science that can be applied to many physical science disciplines.

Chemometrics is a truly interdisciplinary science that draws from mathematics, statistics, and information science; however, the tools from these disciplines cannot be directly applied without sound knowledge and understanding of the chemical system in question. Many statistical tools are useless to chemometricians because the underlying assumptions are violated in the chemical system. Concurrently, a chemometrician could develop very useful “statistical tools” that are not generalizable beyond the chemical system in question. Furthermore, the distinction between “statistical significance” and “practical significance” cannot be reliably made without an understanding of both statistics and chemistry.

1.2 Roles of Chemometrics

1.2.1 Analysis

Historically, most attention has been devoted to the analysis side of chemometrics. Further distinction can be drawn to identify two applications of chemometric analysis: factor analysis (FA) and calibration. FA is most closely derived from other “-metric” sciences: econometrics and psychometrics. The goal of FA is to take a global view of a chemical process and uncover the underlying trends, or factors, that are embedded in a collection of data. These factors lend the chemist insights on the factors that have influenced the process and the information content of the observations employed to monitor the process. Calibration implies a more focused perspective on a chemical process. The goal of calibration is to extract a specific piece of information from a collection of data. Examples include measurements of constituent concentrations and product quality. Consequently, calibration methods are more often applied to chemical sensors designed for monitoring specific quantifiable properties (e.g. moisture, octane number, protein) related to product or process quality.

Owing to the importance of calibration of chemical sensors for process monitoring, the majority of this article will be devoted to calibration. However, the implementation of FA for monitoring industrial processes will also be addressed.

1.2.2 Facilitation

In recent years, the role of chemometrics to facilitate the placement of instrumentation in the field for process monitoring has blossomed. This has been fueled by the realization that instruments are not identical and that the performance of an instrument may change dramatically over time. Consequently, much expense and labor are required to develop a calibration model for each instrument. The expense is magnified when the performance of the instrument changes and a new calibration model must be developed. The goal of chemometrics is to develop compact models that “standardize” the response of any given instrument to an ideal instrument on which the calibration model was developed. Thus, the calibration model is transportable among instruments.

1.2.3 Design

The most underutilized role of chemometrics in process analysis is that of design. Chemometrics is, at its core, an information science. By knowing exactly which information is needed, and not needed, from an analysis, chemometrics provides insights to the measurements that must be made and the type of instrument to make these measurements. This leads to an economy of experimental design and sensor construction. For example, by designing a sensor that relies partially on chemometric signal deconvolution techniques or multivariate calibration, complete physical separation of the analyte from the sample matrix may be avoided. This, in turn, would lead to a sensor that is placed in a sample stream, removing the need for a sampling loop to be installed in the process.

1.3 Soft Modeling Versus Hard Modeling

Philosophically, chemometrics generally employs a “soft modeling” approach to data analysis and calibration. With soft modeling a general class of model is imposed on the data and the parameters of the model are not constrained to be physically meaningful. In contrast, hard models assume that each parameter estimated relates to a physical property. For example, the Beer–Lambert law is a hard model. The parameters estimated (or known) are concentration, path length, and molar absorbitivity. A soft model approach to the Beer–Lambert law problem only says that concentration is somehow related to measured absorbance. Soft modeling has two distinct advantages over hard modeling. First, less needs to be known about the system studied. Soft models can be rapidly developed and tested relative to hard models – if a linear model did not work, try a nonlinear, polynomial, or spline based model. Second, soft models can be applied where no true hard model exists. For example, try to make a model explicitly relating the Raman spectra of gasoline to octane number. Whereas it is difficult to construct a hard model for this relationship, soft model based calibration methods can accurately predict the octane number.
1.4 Chemometric Classification of Data

From a chemometric standpoint, data and instrumentation are often classified based on the dimensionality of the data set obtained. In general, the higher the dimensionality of the data set, the more powerful is the instrument, and consequently more powerful data analysis methods can be applied to higher dimensioned data sets. The different dimensions of data are presented in Figure 1. For a more complete discussion on the interrelationship between data structure and analyzability, see Geladi and Booksh and Kowalski.

The most basic type of data are univariate data. Examples of univariate data are data collected from a pH meter or single-channel photometer. Univariate data are the lowest dimensionality of data – a univariate instrument returns a zero-dimensional (zeroth-order) data tensor. Consequently, a collection of data from a univariate sensor forms a vector and is said to be one-way data, that is, it varies in only one way: sample to sample.

The majority of the literature on chemometrics address the analysis of multivariate data. Examples of multivariate data include chromatograms and spectra. Analysis of a single sample with a multivariate instrument yields a one-dimensional (first-order) data tensor. A collection of samples forms a two-dimensional matrix and is said to be two-way data because it varies from sample to sample and wavelength to wavelength.

Multiway data are formed, for example, by coupled instrumentation such as gas chromatography/mass spectrometry (GC/MS) and excitation–emission matrix spectrometers. Analysis of a single sample yields a two-dimensional (second-order) tensor of data. The key to having true multiway data is that one instrument (or order) must modulate the other instrument (or order). For example, ultraviolet/visible (UV/VIS) spectroscopy coupled with infrared (IR) spectroscopy does not give multiway data because the UV/VIS and IR spectra of a molecule do not modulate each other. A collection of sensor readings during the progression of a batch process do form multiway data (sensors by time). There is no upper limit on the number of “ways” that could go into a data set. Conceivably, one could employ on-line high-performance liquid chromatography (HPLC)/UV/VIS spectroscopy to monitor a series of batch processes; a four-way data tensor results (wavelength by chromatographic retention time by time in the batch by batch).

1.5 Nomenclature

In general, the nomenclature of referring to data as univariate, multivariate, and multiway is adopted in this article. This avoids confusion with the myriad of other mathematical and statistical definitions for “dimension” and “order”. When data for a specific dimension must be identified, the order will be attached as a prefix, e.g. three-way data.

Throughout the article, scalars are italicized. Upper case italics represent fixed values, e.g. J samples. Lower case italics represent variables, e.g. the jth sample. All vectors are column vectors and represented by lower case bold characters, \( \mathbf{r} \). Matrices, second-order tensors, are represented by upper case bold characters, \( \mathbf{R} \), and third-order tensors are represented by bold underlined characters, \( \underline{\mathbf{R}} \). A character with a subscript (or subscripts) is assumed to be the appropriate element from a higher dimensional data matrix. For example, \( \mathbf{R}_{ij} \) is the \( i \)th \( j \)th slice of the tensor \( \mathbf{R} \). The superscript \( T \) indicates the transpose of a matrix or vector, e.g. \( \mathbf{r}^T \). The presence of a bar over a matrix, e.g. \( \overline{\mathbf{V}} \), indicates a reduced space of \( \mathbf{V} \) where just the columns that are deemed useful are considered. A carat overlaying any symbol, e.g. \( \hat{b} \), indicates an estimate of the true value. The superscript \( ^C \) indicates the pseudoinverse or Morse–Penrose inverse of a matrix. The character \( \odot \) indicates the Hadamard product, or element-wise multiplication, of two matrices.

2 UNIVARIATE ANALYSIS

2.1 History and Introduction

Chemists have employed formal univariate data analysis since the beginning of the 20th century. Arguably the first “process chemometrician”, chemist W.S. Gosset,
developed the $t$-test for process quality control while at Guiness in 1908. Since 1908, univariate analysis has matured. Monographs relating statistical methods for chemical process monitoring and optimization have been around since the 1940s\cite{12,13} and there have been few fundamental advances in the last 40 years. However, univariate methods form the basis for most multivariate chemometric techniques. For this reason, a brief overview of univariate analysis methods and theory is provided.

### 2.2 Statistical Analysis

Analysis methods can be divided into two classes, empirical methods and statistical methods. Empirical methods are generally simple and easy to compute. Examples of empirical methods include histograms and box (quartile) plots.\cite{10} While intuitively informative, empirical methods only offer qualitative information regarding the character of a set of observations.

On the other hand, statistical methods are designed to make inferences quantitatively regarding the compliance of the observed data with the assumed nature of the system. This is generally accomplished by making assumptions regarding the probability distribution of random measurement errors. In most popular statistical methods, measurement errors are assumed to follow a normal, or Gaussian, distribution. For Gaussian errors, the mean measurement error is zero and the width of the distribution is defined by the standard deviation. This distribution is employed in Student’s $t$-test to compare means (averages) of observations and in $\chi^2$ and $F$-tests to compare variances (squared standard deviations) of observations. However, “distribution-free” statistical tests that do not make assumptions regarding measurement errors also exist. Further details of univariate statistical tests can be found in elementary statistics texts\cite{12,13} or monographs aimed at chemists.\cite{14,15,16}

There are two univariate statistical tools that resurface with multivariate data analysis methods. The first is means testing with a $t$-test. The Gaussian distribution of measurement errors is implicit with the $t$-test. By estimating, or assuming, the standard deviation of the measurement error, $\sigma$, a probability can be determined that a measurement, $r$, would be at most the observed difference from a true target value, $\mu$, by random chance alone. The probability is given by the fraction of the area under the probability distribution function that is removed from $\mu$. The $t$-test is used for placing confidence limits on statistical process control (SPC) charts and calibration predictions. The second recurring tool is the $F$-test to compare variances. The $F$-distribution is given by the ratio of two $\chi^2$ distributions. (A $\chi^2$ distribution is the sum of squared normally distributed variables.) If two populations have the same standard deviation (i.e. two instrumental methods have the same precision), the ratio of observed measurement variances is expected to be 1. As with the $t$-test, integrating under the probability distribution function yields the probability that the two otherwise identical populations would be observed to have a particular deviation from their expected value. $F$-tests are commonly employed to test the relative performance of competing calibration models. Tables for $t$-test and $F$-test probabilities as a function of number of observations are given in most statistical texts.

### 2.3 Statistical Process Control Charts

The goal of SPC charts is to provide the process engineer with a rapid and intuitive visual method to observe the state of a process. In the univariate case, a statistic is continuously plotted against time during a process run. This statistic can be a single measurement (temperature) or a weighted sum of previous measurements (e.g. an exponentially weighted moving average of the last 20 measured temperatures). The expected mean and standard deviation of the statistic are determined from analysis of past process runs that were “in control”. The probability levels from the statistical analysis of the historical data with a $t$-test serve as warning lines for the process going out of “control”. For example, the 95% probability limit ($t = \mu \pm 1.96\sigma$) might serve as a warning while the 99% probability limit ($t = \mu \pm 2.81\sigma$) might tell the operator to take action.

Figure 2(a) and (b) presents mock SPC charts for a process leaving and re-entering “control”. Figure 2(a) presents the SPC chart plotted for a single measurement while Figure 2(b) presents each point as the mean of the previous five measurements. The historical mean, or target value, for the process is 176. For the first 20 min, the process is “in control”. Note that one of the 20 measurements is outside the 95% probability limit. This is expected owing to normal variation of the process; the next measurement is well within the control limits. However, at time 21 the process begins to creep out of control and begins returning to control at time 40. Note that these trends are evident in both the single measurement and moving window SPC charts; however, the signal averaging with the moving window makes visualization of short-term trends much easier.

### 2.4 Calibration and Prediction

The typical goal of univariate regression is to model the instrumental response, $r$, as a linear function of the property to be estimated (e.g. concentration, $c$). Including a term in the model that accounts for an instrumental baseline, $\beta_0$, yields the classical Equation (1):

$$ r = \beta_0 + c\beta_1 + \varepsilon $$

(1)
Consequently (Equation 4),

$$\hat{b} = [c^0|c^1|\ldots|c^N]^+ r$$  \hspace{1cm} (4)

where “+” indicates that the pseudo-inverse of a matrix is employed to estimate the polynomial coefficients of the regression curve. Estimation of the analyte concentration in a future sample is accomplished by solving Equation (3) for \( c \), given \( r \) and \( \hat{b} \). The statistical and numerical properties of Equation (3) are well documented and covered in most textbooks on linear regression.\(^{17}\)

2.5 Experimental Design

There are two general philosophies for experimental designs in process analysis. The first is exploratory, or discovery, experimental design and the second class is for calibration. For either class of experimental design, the data are collected in only one “way” – by varying the nature of the samples, that is, the same measurement is repeated for a variety of unique samples where each sample has been perturbed in a known manner.

The idea behind exploratory experimental designs is to uncover (and possibly to quantitate), with as few samples as possible, the underlying factors that influence the behavior of the process. Therefore, many factors (e.g. process inputs) are varied for exploratory analysis with the goal of determining which inputs are important. Examples of exploratory experimental designs for modeling the “sample space” include factorial designs and Taguchi designs.\(^{14,18}\) Exploratory experimental designs, such as Fibonacci searches\(^{19}\) and simplex designs\(^{20}\), are commonly employed to optimize a system without explicitly modeling its behavior.

Whereas exploratory analysis is aimed at optimizing a process for the future, the goal of calibration is to predict the state of a sample based on past performance. That is, a model is to be constructed that will allow regression of one observation for estimation of a property of the sample. The application of calibration and prediction is covered in section 2.4. Owing to the different goals of exploratory analysis and calibration, experimental designs for calibration are much more restrictive than exploratory experimental designs. Because only one measurement per sample is to be performed, only one property of the sample can be calibrated with a given experimental design. Consequently, all other factors influencing the state of the system must be held constant for the calibration and estimation samples.

Two particular aspects of experimental design recur for multivariate analysis: leverage and sample spaces. Leverage is a measure of the influence each sample has on the model. For linear univariate calibration the leverage of the \( i \)th sample is based on the distance of the sample
from the mean of the calibration set, \( \bar{r} \) (Equation 5):

\[
I_i = (r_i - \bar{r})^2
\]  

(5)

The greater the total leverage, the more stable is the calibration model, and consequently, the better is the precision of estimation with the calibration model. From this, the astute reader may conclude that it is optimal to have half of the calibration samples at one extreme of the calibration model and half of the calibration samples at the other extreme of the calibration model (Figure 3, circles). However, although this optimizes the experimental design for leverage, the sample space might not be optimally covered. Suppose that the instrumental response to be calibrated is nonlinear. There would be no way to model, or even detect, this nonlinearity with the leverage optimized experimental design. By collecting samples that better fill the sample space, nonlinearities can be detected and modeled (Figure 3, crosses). Optimization of the exact sample placement depends on the formula of the nonlinear curve to be fitted to the data.

It should also be noted that, in many cases of process analysis, the analyst does not have the luxury of applying a truly optimized experimental design. In the extreme case, the analyst has no influence on the experimental design; any variability in the sample space is governed by the inherent variance of the process. Realistically, there is a limited amount of process variance that can be induced by the analyst; however, owing to safety and economic constraints, the process cannot be run outside its normal parameters. In these cases it must be remembered that any models developed are valid only within the sample space. There are no assurances of the applicability of the models outside the range of samples from which the models were based.

2.6 Figures of Merit

In order to compare instrumental methods it is useful to have a handful of objective and quantifiable criteria on which discussion is based. Examples include speed, cost, reliability, precision, sensitivity (SEN), selectivity (SEL), and detection limit of analysis. While speed, cost, and reliability weigh heavily in a process analyst’s decision on which instrumental technique to employ for a particular application, these figures of merit are not intrinsic to a given instrumental method. For example, the cost and speed of analysis largely depend on the number of samples to be analyzed; with large quantities of samples, economic and time savings can be achieved through bulk purchasing and automation. However, the final four figures of merit are intrinsic to the application of an instrumental method and are directly related to the instrumental response for a particular set of analytes.

The SEL is the fraction of the instrumental signal that is unique to the analyte. Assuming that the instrument is “zeroed” to remove any baseline (Equation 6):

\[
SEL = \frac{r_a}{r}
\]  

(6)

where \( r_a \) is the instrumental signal of just the analyte and \( r \) is the instrumental signal of the sample. The SEL is a value between 0 and 1 with SEL = 1 being a fully selective sensor. For univariate calibration an instrument must be fully selective, otherwise a bias will be imbedded in the prediction of future samples. There is no way, based only on statistical analysis of collected data, to determine the contribution (or existence) of nonselective interferents in any given “unknown” sample.

The SEN is the change in instrumental response with respect to changes in analyte concentration (Equation 7):

\[
SEN = \frac{\delta r}{\delta c}
\]  

(7)

For linear calibration, this is the slope of the calibration curve.

The precision of a method is best expressed in the signal-to-noise ratio (S/N) (Equation 8):

\[
S/N = \frac{r_a}{e}
\]  

(8)

where \( e \) is a measure of the reproducibility of replicated measurements. In many cases, the measurement reproducibility is not concentration dependent (e.g. for thermal noise limited analyses). In this case S/N will vary with analyte concentration.

The limit of detection (LOD) is defined by the International Union of Pure and Applied Chemistry
3 MULTIVARIATE ANALYSIS

3.1 History and Introduction

The success of multivariate chemical analysis is based on three facts. First, most, if not all, chemical processes are multivariate in nature. Consequently, to be able to monitor and model a multivariate process effectively, multivariate data regarding that process must be collected and analyzed. Second, even if only a single piece of information is needed from a chemical system, it is very difficult to design a sensor that is fully selective to the property of interest. Therefore, to circumvent the lack of fully selective sensors, arrays of partially selective sensors can be constructed that rely on multivariate analysis methods to extract the information of interest. Third, there are inherent advantages associated with the redundancy of data when there are many more variables measured per sample than samples collected.

Initially, chemometrics relied heavily on mathematical and statistical methods developed for analyses of biological, economic, and psychological data. In the 1970s, a few academic teams were investigating the benefits of multivariate analysis for instrument calibration. Perhaps overplaying the field, it was envisioned that multivariate data analysis and calibration methods would make most instrumental methods (such as chromatography) obsolete. However, the impact of multivariate data analysis and calibration on process analytical chemistry was negligible.

As personal computers became increasingly powerful and less expensive and chemists began to develop an appreciation for the benefits derived from multivariate analysis and an understanding of the limits of multivariate analysis, multivariate methods slowly became accepted in industry. Not coincidentally, the acceptance of multivariate analysis coincided with the rise of the process analytical chemistry philosophy. Most of the sensors designed for on-line, in situ, or noninvasive analysis require multivariate analysis for calibration or data interpretation. This section presents the basic outline for application of the multivariate method useful in process analysis. Particular attention is directed to discussing the utility of selected multivariate methods as they apply to process analysis.

3.2 Factor Analysis

FA is employed to aid in the visualization of sample (time)-dependent trends and measurement (sensor)-dependent trends in a multidimensional data space. In general, FA does not give a physically meaningful model – only correlations among samples and measurements are determined. However, FA methods have been modified to apply constraints and assumptions based on previous knowledge of the chemical system being analyzed. These modified FA methods are useful for determining the underlying instrumental and/or sample (time) profiles of the chemical constituents of a process.

3.2.1 Principal Component Analysis

Perhaps the most commonly applied method of FA is principal component analysis (PCA). Most chemometrics-oriented monographs have sections dedicated to PCA. The goal of PCA is to identify the major sources of correlated variance in a collection of data. Once these sources of variance have been identified, they can be exploited to aid in the visualization of the major trends throughout the data collection. The data collection can be reduced from a complicated multidimensional representation (a 1024-channel spectrum is actually a vector in 1024-dimensional space) to a more easily visualized two- or three-dimensional space that describes the majority of the variance (information) in the data collection.

The conceptual idea behind PCA is presented in Figure 4. The largest direction of variance in the data collection is the first principal component (PC). The second PC is defined to describe the maximum amount of variance in the data collection while constrained to be orthogonal to the first PC. Consequently, each additional PC is also defined to maximize variance described while constrained to be orthogonal to all preceding PCs. Note that the PCs are defined as vectors originating at the origin of the coordinate space. Therefore, the PCs are dependent on the average value of the data collection; translating the data cloud to a different point in the coordinate space changes the direction of the PCs. For this reason, the data collection is often translated to be centered about the origin of the coordinate space (see section 5.1). However, the location of the data collection does not affect the ability of PCA to model the data variance. Only the ease of interpreting the model is affected.

\[
\text{LOD} = \frac{3e}{\beta_1} \quad (9)
\]

where \(\beta_1\) is the slope of the calibration.\(^{(22)}\)
3.2.1.1 Determination of Principal Components

PCA is a form of eigenanalysis where a matrix of data $\mathbf{R}$ is decomposed into the product of two (or three) matrices. The most common matrix representations employed for PCA are (Equations 10 and 11)

$$\mathbf{R} = \mathbf{T} \mathbf{P}^T$$  \hspace{2cm} (10)

and

$$\mathbf{R} = \mathbf{U} \mathbf{S} \mathbf{V}^T$$  \hspace{2cm} (11)

where each of the $I$ rows of $\mathbf{R}$ consists of the $J$ measurements performed on the $I$ samples. Graphically, Equation (11) is illustrated in Figure 5. In practice, the factorization of $\mathbf{R}$ in Equations (10) and (11) can be performed by iterative algorithms that are found in most numerical analysis toolboxes. The most numerically stable method is the SVD.\(^{(19)}\)

The $n$th column of the matrices $\mathbf{P}$ and $\mathbf{V}$ are the loadings of the $n$th PC and describe the inter-relationships among the $J$ measurements. The matrices $\mathbf{P}$ and $\mathbf{V}$ are identical. The columns of the matrices are the orthonormal eigenvectors of the covariate matrix $\mathbf{R}^T \mathbf{R}$. Consequently, $\mathbf{P}$ and $\mathbf{V}$ describe the “measurement space” of $\mathbf{R}$. Positive values are all positively correlated with the direction of variance described by a given PC; negative values are negatively correlated with the direction of variance described by the PC. For example, if a PC is found to describe the variance caused by a process upset, sensor readings that increase during (or preceding) the upset will all have the same sign in the loading. Sensors that decrease during the upset will have the opposite sign. Sensors that do not vary as a result of the upset will have loadings near zero on this PC. The absolute sign of the PC is arbitrary; any PC can be equivalently expressed by reversing all signs.

Equations (10) and (11) differ only in the factorization of the “sample space”. In Equation (10), the inter-relation among the samples is expressed as the orthogonal column matrix $\mathbf{T}$. Because the columns of $\mathbf{P}$ are normalized to unit length, the “scores” matrix, $\mathbf{T}$, also contains information regarding the scale of the data matrix, $\mathbf{R}$. By contrast, in Equation (11), the orthonormal columns of $\mathbf{U}$ contain the inter-relation among the samples that constitute $\mathbf{R}$. The columns of $\mathbf{U}$ are the eigenvectors of the covariance matrix $\mathbf{R} \mathbf{R}^T$. The diagonal matrix, $\mathbf{S}$, contains the scale of the data matrix $\mathbf{R}$. The squared diagonal elements of $\mathbf{S}$ are the eigenvalues of the covariance matrices $\mathbf{R}^T \mathbf{R}$ and $\mathbf{R} \mathbf{R}^T$. The scores of Equations (10) and (11) are related by Equation (12):

$$\mathbf{T} = \mathbf{U} \mathbf{S}$$  \hspace{2cm} (12)

3.2.1.2 Nomenclature of Principal Component Analysis

The theory and development of PCA can be traced in the mathematics, statistics, and social science literature. Consequently, the nomenclature employed by any given author will depend greatly on the author’s previous background and exposure to PCA. Table 1 presents a compilation of the descriptive terms employed in the various fields. Of note are the social science terms “score”

and “loading”. These terms reveal the anthropologist Sir Francis Galton’s assumption that there are certain latent factors that are “loaded” into each person. These latent factors are common throughout the population in general and give rise to each person’s individual personality. The greater an underlying trait is exhibited by a person, the higher the person’s “score” for that trait would be. As a side note, the term “regression” also comes from the psychological literature. It was postulated, and disproved, that children of extraordinary parents tended to “regress to the mean” of the population.\(^{(27)}\)

### 3.2.1.3 Interpretation of Principal Component Analysis

There are two important facts to remember when interpreting PCA models. First, the factorization of \(\mathbf{R}\) is arbitrary; there are infinite factorizations that equivalently model \(\mathbf{R}\). PCA is one particular factorization that satisfies the constraints of orthogonal factors and progressive modeling of variance. All other equivalent models that can be constructed are rotations of the eigenspace determined by PCA. Therefore, the loadings are not necessarily, for example, spectra and cannot be interpreted as spectra, even though they often resemble spectral features. Furthermore, the factors do not necessarily describe any single underlying latent physical feature. PCA is purely a correlation based model that describes observed variance. Any causality inferred from the model is implied by the analyst.

Second, not all of the factors determined by PCA describe chemically relevant variance. Some factors describe systematic variance that results from instrumental or sampling artifacts. Also, some factors describe random measurement and sampling errors. The success of PCA lies in the ability of the analyst to discriminate between these three sources of variance. In general, the chemically relevant variance and any systematic variance from instrumental and sampling artifacts are convolved in the first few PCs. Derivatives of PCA such as target factor analysis (TFA) (section 3.2.2), curve resolution (CR) methods (section 3.2.3), and evolving factor analysis (EFA) methods (section 3.2.4) aid the analyst in divining the true, chemically relevant, factors. Section 6.1 addresses determination of systematic factors versus random factors.

### 3.2.2 Target Factor Analysis

As mentioned in the previous section, the latent factors derived from PCA do not necessarily describe single, physically meaningful, effects. That is, while a set of data may consist of the near-infrared (NIR) spectra of hydrocarbon mixtures, the PCs of the data set are not constrained to be NIR spectra of the constituent hydrocarbons. However, the multivariate space defined by the PCs is the same as the multivariate space defined by the pure (true) spectra of the chemical constituents of the data set (plus any other forms of systematic variance).

TFA is a method of testing whether the spectrum of a hypothesized chemical constituent, as defined by an assumed or a priori recorded spectrum, lies in the PC space of the model. If the hypothesized constituent does lie in the PC space, the associated spectrum can be expressed as a linear combination of the PC loadings. That is (Equation 13),

\[
\hat{y} = \mathbf{V} \mathbf{t}
\]

where \(\hat{y}\) is the estimated spectrum of the hypothesized compound and \(\mathbf{t}\) is the transformation vector [not to be confused with \(\mathbf{T}\) in Equation (10)]. The transformation vector can be calculated by regression of the target spectrum, \(\mathbf{y}\), on to the loadings \(\mathbf{V}\). However, the calculation of \(\mathbf{t}\) can also be circumvented by direct projection of \(\mathbf{y}\) into the space defined by the loadings (Equation 14):

\[
\hat{y} = \mathbf{V}^{\mathsf{T}} \mathbf{y}
\]

The presence or absence of \(\mathbf{y}\) in \(\mathbf{R}\) is tested by comparing \(\mathbf{y}\) with the projection of \(\mathbf{y}\) into the factor space, \(\hat{\mathbf{y}}\). If \(\mathbf{y}\) and \(\hat{\mathbf{y}}\) are determined to be sufficiently similar by a statistical or empirical test,\(^{(25)}\) analogous equations can be constructed that project sample targets on to the scores of \(\mathbf{R}\).

### 3.2.3 Curve Resolution

Where TFA allows the analyst to test for the presence of a hypothesized constituent, TFA is limited in the ability to estimate the spectral profile of any constituents in the data set. TFA requires that the spectral profile of the target is available for target testing. If the profile is unavailable, TFA cannot be performed. On the other hand, CR methods allow for the estimation for both the hypothesized and unknown constituents in the data matrix. The rotational ambiguity of the decomposition in Equations (10) and (11) is circumvented by making assumptions regarding the nature of the true constituent spectral profiles (and sample profiles). These assumptions are translated into constraints applied to the factorization of \(\mathbf{R}\). Once additional constraints are applied to the factors of \(\mathbf{R}\), the factors are not true PCs. These factors are properly described as latent variables or intrinsic factors, but not PCs.

#### 3.2.3.1 Constraints

Numerous constraints have been applied to the factorization of \(\mathbf{R}\) to enhance the probability that the determined factors will be physically meaningful. Perhaps the most common constraint is non-negativity of estimated spectral and sample profiles.\(^{(28–33)}\)
This constraint is based on the commonsense notion that the factorization of Equation (10) should lead to spectral estimates (columns of $P$) and concentration estimates (columns of $T$). In neither case would the true profile likely contain negative values. Another common spectral constraint employs assumptions regarding the content of $R$. If the spectral profile of one or more of the assumed chemical constituents is known, the factorization of Equation (10) can be constrained to contain the assumed spectral profiles in the solution.

It is also possible to employ assumptions regarding the inter-relationship among the samples (rows of $R$). For resolving overlapping chromatographic peaks, Gaussian or unimodal elution profiles are assumed for the columns of $P$.\textsuperscript{31,33,34} Concurrently, the presence of samples (rows of $R$) that contain only one compound may be successfully postulated for chromatographic or kinetic data.\textsuperscript{31,35} This is referred to as the “uniqueness” constraint. If the concentration of one or more compounds is known in any of the particular samples, the resolved profiles can be constrained to reflect this information. For kinetic data, the sample profiles can be constrained to fit a class of differential equations that reflect the postulated reaction pathway.\textsuperscript{36,37} The validity of the assumed reaction can be tested based on the ability of the data to fit this model.

Of course, application of other constraints and the combination of multiple constraints are possible. Constraining the FA solutions does not ensure that physically meaningful profiles will be determined. In general, application of constraints only reduces the range of feasible solutions where, ideally, the true profiles will lie within this range. The more constraints are properly applied to the decomposition, the tighter the estimated range of profiles will resemble the true profiles. However, if a constraint is improperly imposed (e.g. nonnegativity when in fact the profile should have negative values) the estimated profiles will yield erroneous profiles.

3.2.3.2 Direct Methods The application of constraints for estimation of spectral profiles can best be seen in the CR method developed by Lawton and Sylvestre.\textsuperscript{28} Lawton and Sylvestre CR was originally applied to binary mixtures. After normalization of each collected spectrum to unit area (section 5.1), the data are factored by Equation (10). Plotting the scores of the first PC versus the scores of the second PC yields a straight line for a binary mixture (Figure 6). The extreme points along the array represent the most pure of the analyzed samples. These form the “inner bounds” of the estimated profiles. The “outer bounds” are calculated by extrapolating the scores line (dotted) and reinflating the scores into the original data space to calculate estimates of the pure spectra (Equations 15 and 16):

\begin{equation}
\hat{y}_b = p_{1a}t_1 + p_{2a}t_2
\end{equation}

\begin{equation}
\hat{y}_o = p_{1b}t_1 + p_{2b}t_2
\end{equation}

In these equations, values for $(p_{1a}, p_{2a})$ and $(p_{1b}, p_{2b})$ are chosen as the extreme points along the extrapolation of the best-fit line in Figure 6 ($p_1$ vs $p_2$) that do not result in negative values in the estimates of pure spectra.

Consequently, the only constraint that Lawton and Sylvestre CR applies to the data is nonnegativity of spectral estimates. When there is at least one spectral channel that is unique to the analyte, then the outer bounds will be the true constituent spectral profile. This CR technique has been generalized to three-component mixtures.\textsuperscript{38} However, the bounds of the potential spectra are generally too large with tertiary mixtures for this CR method to be of much utility.

3.2.3.3 Iterative Methods Practically, iterative CR methods are capable of resolving much more complicated mixtures than are the direct CR methods. Iterative methods make assumptions regarding both the spectral space profiles of the data and the sample space profiles of the data. The constraints resulting from these assumptions are particularly powerful when well-ordered data, such as kinetics or chromatographic data, are submitted. A description of the potential constraints applied to kinetic or chromatographic systems is covered in section 3.2.3.1.

Iterative CR methods employ the bilinear factorization model in Equation (17):

\begin{equation}
R = X Y^T + E
\end{equation}

where the $N$ columns of $\hat{X}$ and $\hat{Y}$ are estimates of the true sample (concentration) and spectral profiles of the $N$ constituents of $R$. $X$ and $Y$ are determined by an alternating least-squares (ALS) algorithm. This algorithm starts with an estimate of either $X$ or $Y$. Assuming an
The method iterates by alternating calculating constrained updates of \( \mathbf{X} \) and \( \mathbf{Y} \) until further refinement does not significantly change the model.

One common iterative method is EFA,\(^\text{[29,34,39]}\) which employs the ALS optimization at its core. The unique feature of EFA is the use of eigenanalyses to determine the initial \( \mathbf{X} \). The singular values are calculated from analysis of the first \( j \) samples. These “forward eigenvalues” are plotted against \( j \) as \( j \) is increased from 1 to \( J \), the number of samples. Concurrently, the “backward eigenvalues” are calculated from analysis of the last \( J - j \) samples as \( j \) increases from 1 to \( J \). These eigenvalues are plotted against \( J - j + 1 \).

This plot of eigenvalue versus sample set yields an estimate of the number of significant factors in \( \mathbf{R} \) and a rough estimate of the sample profiles. The \( N \) significant eigenvalues will be relatively large compared with the remaining eigenvalues and exhibit greater variance throughout the range of \( j \). The area under the intersection on the \( n \)th forward and \( (N - n + 1) \)th backward eigenvalue versus \( j \) plot yields the estimate of the \( n \)th sample profile. These sample profiles are employed as starting guesses for the ALS loop of the EFA method.

### 3.3 Multivariate Statistical Process Control Charts

When multiple measurements are collected throughout a process, it is impractical to monitor simultaneously a distinct SPC chart for every measurement. A more optimum course of action is to construct a smaller set of control charts. In this smaller set, each chart would weigh an ensemble of measurements that correlate to important trends in the process. One way to accomplish this is to form multivariate statistical process control (MSPC) charts.\(^\text{[40–42]}\) Whereas univariate SPC charts plot just a single measurement versus time, MSPC charts first employ FA to condense the information in the measurements into a smaller set of significant factors, and then the observed contribution of these factors in each set of measurements is plotted versus time.

The simplest form of MSPC chart would apply PCA to historical runs of a given process to determine the significant factors that occur (loadings). When monitoring the process in the future, each set of measurements, \( \mathbf{r} \), is projected on to each loading. The magnitudes of these projections (scores) (Equation 20):

\[
t_n = \mathbf{p}^T \mathbf{p} (\mathbf{p}^T \mathbf{p})^{-1}
\]

are plotted for each of the \( N \) factors as a function of time. This yields an indication of the magnitude of each factor at a given time during the process run. Probability limits can be assigned based on variance in the factors of the historical data.

Iterative FA techniques can also be applied to construct MSPC charts. These methods can be employed to model a process dynamically as new species (factors) are formed. Each new set of measurements is augmented to the existing collection of data from the process run and the data are reanalyzed. If an additional factor is warranted one is added to the model. The sample profiles are updated as the new measurements are collected.

When constructing control charts from multivariate data, the Hotelling’s \( T^2 \) statistic provides an important test to check for multivariate normality of the data. The Hotelling’s \( T^2 \) test is the multivariate analog for the Student’s \( t \)-test. The \( T^2 \) statistic for the \( n \)th sample is calculated from the factorized data by the sum of the squared (normalized) scores (Equation 21):

\[
T_n^2 = \sum_{n=1}^{N} \mathbf{u}_m^2
\]

from an \( N \) factor model. The scaled statistic \( T^2/\{1 - (I - N)/(N(I^2 - 1))\} \) follows an \( F \)-distribution with \( N \) and \( I - N \) degrees of freedom.

Process upsets and sensor failures can be identified by examining the residuals derived from projecting future samples onto the FA model constructed from archival data (Equation 22):

\[
\mathbf{e}_r = \mathbf{r}^T (\mathbf{I} - \mathbf{N}\mathbf{V}^T)
\]

where \( \mathbf{N} \) represents the set of columns in the loading matrix that are “significant” in describing the process and \( \mathbf{I} \) is an appropriately dimensioned identity matrix. Whether the sample \( \mathbf{r} \) lies outside the space of the model can be investigated by comparing the magnitude of \( \mathbf{e}_r \).
with the magnitude of the residual error of the model (Equation 23):

$$E_R = R^T(I - \mathbf{VV}^T)$$  \hspace{1cm} (23)$$

Adjusting for number of observations and degrees of freedom, an approximate F-statistic (Equation 24)

$$F = \frac{\|e\|_F^2}{(J - N - 1)(J - N)} \frac{\|E_R\|_F^2}{\|E\|_F^2}$$  \hspace{1cm} (24)$$
can be constructed with $(J - N)$ and $(J - N - 1)(J - N)$ degrees of freedom, where $\| \cdot \|_F$ is the Frobenius norm (root sum of squared elements) of a matrix.

### 3.4 Calibration and Prediction

The instrumental response of a mixture measured at a single variable relies on the classical least-squares (CLS) model (Equation 25):

$$r = Cs$$  \hspace{1cm} (25)$$

where $r$ is the instrument response from a number of samples, $C$ is a matrix (samples x constituents) of the extrinsic property of interest (often concentration) and $s$ is an intrinsic property (often spectral in nature) that relates the rows of $C$ to $R$. This follows a logical Beer's law type of model where the instrument response is expressed as a function of the constituent's concentration and spectra. Equation (25) is readily expanded to multivariate–multianalyte analysis (Equation 26):

$$R = CS^T + E$$  \hspace{1cm} (26)$$

where each row of $R$ is the spectrum of the mixture of constituents defined by the appropriate row of $C$. The constituent spectra lie in the columns of $S$.

Calibration and prediction with Equation (26) are accomplished by multilinear regression (MLR)). For a set of recorded spectra, $R$, with known constituent extrinsic properties, $C, S$ can be estimated by ordinary least-squares inversion of $C$ (Equation 27):

$$S^T = C^+ R$$  \hspace{1cm} (27)$$

Premultiplication of a future recorded spectrum, $r_{un}$, by the (pseudo)inverse of $S$ affects the estimation of extrinsic properties in the unknown sample (Equation 28):

$$\hat{c}_{un} = \hat{S}^T r_{un}$$  \hspace{1cm} (28)$$

Consequently, there are advantages and disadvantages associated with MLR. The primary advantage is that estimates of the true constituent spectra are derived during calibration. However, MLR requires knowledge of the concentrations of all constituents with a spectral profile in the calibration set. From a practical standpoint, this may be an unreasonable requirement. In many cases, e.g. spectroscopic estimation of octane number or Reed vapor pressure, no “spectrum” of the extrinsic property would exist. The second disadvantage is that, in determining $S$ by least squares in Equation (27), it is assumed that the errors in $R$ are much greater than the errors in $C$. This is not usually the case in chemical applications.

Employing an inverse least-squares (ILS) model alleviates the need for complete knowledge of the calibration set constitution. With the ILS model, concentration (or any intrinsic property) is modeled as a function of instrument response (Equation 29):

$$c = Rb$$  \hspace{1cm} (29)$$

where the vector $b$ relates the variance in the observed data, $R$, to $c$. The “regression vector” $b$ is chosen to be correlated with $c$ and contravariate (orthogonal) to all sources of variance in $R$ that are not correlated with $c$. This regression vector is purely a mathematical construct and has no physical meaning. By employing such “soft modeling” calibration based on correlation, knowledge of only the extrinsic property of interest to be estimated is required for calibration.

Figure 7 presents the concept of a contravariate regression vector in a two-dimensional space. Note that the regression vector for analyte A is orthogonal to that for analyte B. Were a different species present instead of B, then the regression vector for A would be slightly rotated to maintain orthogonality. The projection of A on to the regression vector is said to be the net analyte signal (NAS). The NAS is the part of A that is employed.
for calibration. In general, the larger the NAS the more stable is the regression model. The role of NAS is further discussed in section 3.5.

This section presents the formulation of common linear and nonlinear calibration methods that employ the ILS procedure. The successful application of the methods often depends on judicious preprocessing of the recorded variables and choice of model complexity. These two topics are covered in sections 5 and 6, respectively.

3.4.1 Linear Methods

3.4.1.1 Principal Components Regression

One common and robust ILS calibration method is principal component regression (PCR)\(^{(26,44–46)}\). In essence, PCR performs calibration with the scores from the PCA decomposition of \(\mathbf{R}\). The first step of PCR is factorization of \(\mathbf{R}\) by Equation (11). Once the number of significant factors has been determined, error reduction is accomplished by discarding factors that describe random variance. Thus (Equation 30)

\[
\mathbf{R} \approx \mathbf{U} \mathbf{S} \mathbf{V}^T = \tilde{\mathbf{R}}
\]

Because PCR [and partial least-squares regression (PLSR) below] discard variance from the calibration \((\text{truncated columns of } \mathbf{U} \text{ and } \mathbf{V})\) set prior to regression, these methods are said to be biased. However, any loss of accuracy is compensated by an improvement in precision. The net result is a general lessening of prediction errors compared with employing all of the variance of \(\mathbf{R}\) in calibration.

The second step in PCR is the estimation of the regression vector \(\mathbf{b}\). Either a subset of the scores, \(\mathbf{U}\), or the random error reduced response matrix, \(\mathbf{R}\), can be related to the dependent variable, \(\mathbf{c}\). However, both options are equivalent. The orthonormal character of the scores and loadings makes estimation of \(\mathbf{b}\) trivial once \(\mathbf{R}\) has been factorized by Equation (11). Because both \(\mathbf{U}^T \mathbf{U}\) and \(\mathbf{V}^T \mathbf{V}\) are identity matrices (Equation 31):

\[
\mathbf{b} = \tilde{\mathbf{R}}^T \mathbf{c} = \mathbf{V} \mathbf{S}^{-1} \mathbf{U}^T \mathbf{c}
\]

where the inverse of the square diagonal matrix \(\mathbf{S}\) is the inverse of the elements along the diagonal. Estimation of \(\mathbf{c}\) for future samples is accomplished by multiplication of the regression vector with the recorded instrumental response of the sample in question (Equation 32):

\[
\hat{\mathbf{c}}_{\text{un}} = \mathbf{r}_{\text{un}}^T \mathbf{b}
\]

3.4.1.2 Partial Least-squares Regression

PLSR\(^{(45–48)}\) has been employed since the early 1980s and is closely related to PCR and MLR.\(^{(34,45)}\) In fact, PLSR can be viewed as a compromise midway between PCR and MLR.\(^{(49)}\) In determining the decomposition of \(\mathbf{R}\) (and consequently removing unwanted random variance), PCR is not influenced by knowledge of the estimated property in the calibration set, \(\mathbf{c}\). Only the variance in \(\mathbf{R}\) is employed to determine the latent variables. Conversely, MLR does not factor \(\mathbf{R}\) prior to regression; all variance correlated with \(\mathbf{c}\) is employed for estimation. PLSR determines each latent variable to optimize simultaneously variance described in \(\mathbf{R}\) and correlation with \(\mathbf{c}\). Technically, PLSR latent variables are not “principal components”. The PLSR factors are rotations of the PCA PCs for a slightly different optimization criterion.

Mathematically, the first PLSR loading is determined to maximize Equation (33):

\[
(\text{VAR} \times \rho)^2 = (\mathbf{p}^T \mathbf{p})^2 \frac{(\mathbf{p}^T \mathbf{c})^2}{(\mathbf{p}^T \mathbf{p})(\mathbf{c}^T \mathbf{c})} = \frac{\mathbf{u}^T \mathbf{u}}{\mathbf{c}^T \mathbf{c}}
\]

which can be expressed in terms of Equation (10) or (11). Successive PLSR loadings maximize Equation (33) under the constrained orthogonality to prior PLSR loadings. PLSR scores are determined by projection of \(\mathbf{R}\) on to the PLSR loadings. The PLSR factors are determined by iterative algorithms that are described in most chemometric texts\(^{(3,4,16,25)}\) and elsewhere.\(^{(44–46)}\) In fact, numerous algorithms exist that are optimized for various sizes of \(\mathbf{R}\).\(^{(50,51)}\)

PLSR has two distinct advantages over PCR. First, PLSR generally provides a more parsimonious model than PCR. PCR calculates factors in decreasing order of R-variance described. Consequently, the first factors calculated, that have the least imbedded errors, are not necessarily most useful for calibration. On the other hand, the first few PLSR factors are generally most correlated with concentration. As a result, PLSR achieves comparable calibration accuracy with fewer latent factors in the calibration model. This further results in improved calibration precision because the first factors are less prone to imbedded errors than are lower variance factors.

Second, the PLSR algorithm is often faster to implement and optimize for a given application than is the PCR algorithm. PLSR calculates the factors one at a time. Hence only the latent variables needed for calibration are determined. PCR, employing the SVD, calculates all possible PCs for \(\mathbf{R}\) prior to regression. For large data sets that require relatively few factors for calibration, PLSR can be significantly faster than PCR.

3.4.1.3 Locally Weighted Regression

The global linear models calculated by PCR and PLSR are not always the best strategy for calibration. Global models span the variance of all the samples in the calibration set.
If the data are nonlinear (a Beer’s law type of relationship between constituents, spectra, and predicted property does not hold) then the linear PCR and PLSR methods do not efficiently model the data. One option is to employ nonlinear calibration methods. Nonlinear methods employ a global, nonlinear model and are discussed in section 3.4.2. The second option is to employ linear calibration methods on small subsets of the data.

The locally weighted regression (LWR) philosophy assumes that the data can be efficiently modeled over a short span with linear methods. The first step in LWR is to determine the \( N \) samples that are most similar to the unknown sample to be analyzed. Similarity can be defined by distance between samples in the spectral space, by projections into the PC space, and by employing estimates of the property of interest. Once the \( N \) nearest standards have been determined, either PLSR or PCR is employed to calculate the calibration model.

LWR has the advantage of often employing a much simpler, and more accurate, model for estimation of a particular sample. However, there are three disadvantages associated with LWR. First, two parameters must be optimized for LWR, number of local samples and number of factors, compared with just one parameter for PLSR and PCR. Second, a new calibration model must be determined for every new sample analyzed. Third, LWR often requires more samples than PCR or PLSR in order to build meaningful, local calibration models.

### 3.4.2 Nonlinear Methods

Numerous nonlinear, multivariate calibration methods have been described in the chemometric literature. These methods can be divided into two classes. Alternating conditional expectations (ACE)\(^{(37,58)}\) and projection pursuit (PP)\(^{(59)}\) seek to transform the nonlinear data such that a linear calibration model is appropriate. Similarly, global linearizing transformations (GLT) are employed to optimally linearize data prior to FA by PCA.\(^{(60,61)}\) On the other hand, nonlinear partial least squares (NPLS),\(^{(62,63)}\) multivariate adaptive regression splines (MARS),\(^{(64,65)}\) and artificial neural network (ANN) methods determine nonlinear global models that span the entire range of samples. Although it is impossible to provide sufficient detail for each method in this article, some general comments regarding the application of these nonlinear methods are warranted.

Specific nonlinear methods have been compared and contrasted over a wide variety of linear and nonlinear calibration applications.\(^{(66–68)}\) No single method has demonstrated systematic superiority over the other methods. The safe conclusion is that calibration method superiority is application dependent. When the underlying type of nonlinearity implicit in the calibration method matches the latent nonlinearity in the data, the method will optimally model the data. This assertion has been supported by the improvement in calibration performance when theoretical instrument response functions replace the sigmoidal transfer function in ANN calibration.\(^{(71)}\)

Nonlinear methods are much more prone to “overfitting” the calibration model. Overfitting occurs when the calibration begins to employ random variance (instrumental errors) for determining calibration parameters. The flexibility of the nonlinear models and the relatively large number of parameters that need to be estimated are the primary causes of this phenomenon. Consequently, the more complicated the model, the more prone the method is to overfitting (e.g. ANN vs PCR). A decision tree based on Occam’s Razor has been proposed to aid chemists in choosing among the nonlinear methods.\(^{(69)}\) Linear and nonlinear calibrations were linked in a hierarchical web. The hierarchy is based on nested models and degrees of freedom required to calculate the model. Simple, linear models are at the top of the hierarchy and complex, nonlinear methods are at the bottom. It is recommended that to guard against overfitting and spurious modeling of the data, the method nearest the top of the hierarchy that provides sufficient calibration reliability for the application be employed. That is, use the simplest model that works.

### 3.5 Figures of Merit

The figures of merit for multivariate calibration are analogous to those for univariate calibration, with two notable exceptions. First, multivariate figures of merit are based on the ILS calibration model where univariate figures of merit are derived from the CLS calibration model. Therefore, the relationship between the model and the figures of merit may seem inverted when comparing univariate figures of merit with multivariate figures of merit. Second, multivariate figures of merit are based on the NAS compared with univariate figures of merit which are based on the total analyte signal.

The NAS, as defined in section 1.4, is the part of the analyte signal that is used for calibration. This is the analyte signal that is orthogonal to the signal from all other constituents. Mathematically, the NAS can be calculated by projecting the analyte signal on to the space defined by the other constituent signals (Equation 34):

\[
\text{NAS} = (\mathbf{I} - \mathbf{R}_a\mathbf{R}_a^+\mathbf{r}_a)
\]

where \( \mathbf{I} \) is the appropriately sized identity matrix, \( \mathbf{R}_a \) is a matrix of spectra without the analyte, and \( \mathbf{r}_a \) is the
spectrum of the analyte of interest. The NAS is related to the regression vector, \( \mathbf{b} \), by Equation (35):

\[
\mathbf{b} = \frac{\text{NAS}}{\|\text{NAS}\|_2}
\]

(35)

with \( \| \cdot \|_2 \) being the Euclidean norm, or 2-norm, of a vector. Consequently, multivariate figures of merit can be expressed in terms of either the NAS or \( \mathbf{b} \). It is important to note that the NAS changes with the constituents of the calibration set. If more constituents are added, or constituents with increasing signal correlation to the analyte are substituted, the magnitude of the NAS will decrease.

In order to determine the figures of merit, it is unnecessary to determine the NAS. In fact, only the Euclidean length of the NAS is needed. This value can be determined from the regression vector by Equation (36):

\[
\|\text{NAS}\|_2 = \frac{1}{\|\mathbf{b}\|_2}
\]

(36)

The figures of merit can be defined either in terms of unit concentration (Equation 37) or in terms of arbitrary concentration. Here, for the sake of simplicity, they will be defined in terms of unit analyte concentration.

The SEN of a multivariate method, at unit concentration, is the norm of the NAS (Equation 37):

\[
\text{SEN} = \|\text{NAS}\|_2 = \frac{1}{\|\mathbf{b}\|_2}
\]

(37)

because only the NAS is employed for estimation. Similarly, the effective S/N for multivariate calibration (at unit concentration) is given by Equation (38):

\[
\text{S/N} = \frac{\|\text{NAS}\|_2}{\|\mathbf{e}\|_2} = \frac{1}{\|\mathbf{e}\|_2\|\mathbf{b}\|_2}
\]

(38)

where \( \mathbf{e} \) is a vector of independent, identically distributed measurement errors associated with \( \mathbf{r} \). If three standard deviations of the instrumental blank are recognized as the smallest detectable signal, the IUPAC LOD is calculated as (Equation 39)

\[
\text{LOD} = \frac{3\|\mathbf{e}\|_2}{\|\text{NAS}\|_2} = \frac{3\|\mathbf{e}\|_2\|\mathbf{b}\|_2}{\|\text{NAS}\|_2}
\]

(39)

Actually, these definitions of S/N and LOD are rather optimistic because most real errors increase with \( \mathbf{r} \). Therefore, for mixtures \( \|\mathbf{e}\|_2 \) will be larger than would be predicted from the magnitude of \( \mathbf{r} \) alone.

SEL is defined in univariate calibration as the fraction of the sample signal that comes from the analyte. This value ranges from zero to one. In multivariate calibration, SEL is defined as the fraction of the analyte signal that is useful for calibration. Because the NAS is the part of the useful analyte signal, a ratio of the 2-norm vector yields the SEL (Equation 40):

\[
\text{SEL} = \frac{\|\text{NAS}\|_2}{\|\mathbf{r}_a\|_2} = \frac{1}{\|\mathbf{b}\|_2\|\mathbf{r}_a\|_2}
\]

(40)

The multivariate SEL also ranges from zero to one. A SEL of 1 implies that the analyte response is completely orthogonal to all recorded interfering signals. A SEL of zero indicates that the analyte’s response is completely correlated with the other constituents and reliable calibration is impossible. Reliable calibration may be accomplished with a SEL greater than zero; however, the larger the SEL, the more stable is the calibration. However, for applications where no true analyte spectrum exists, e.g. octane number, SEL cannot be defined.

4 MULTIWAY ANALYSIS

4.1 History and Introduction

Multiway analysis became popular in the late 1970s in the psychometric literature. These psychologists employed the multiway models primarily for FA – to determine intrinsic factors in large, complex data sets. However, as chemical instrumentation advanced with automated data collection, chemists began to possess large, multiway data collections. In 1980 Hirschfeld listed 66 instruments capable of generating multiway data. Geladi cataloged the manners in which multiway data can be collected in chemical applications.

It is difficult to discern which multiway methods are “factor analysis” methods and which methods are “calibration” methods because FA is implicit in the multiway calibration philosophy. In this work, the distinction between FA and calibration is made based on the primary applications of each method. Those methods that are commonly employed when factor analytic information is desired are designated FA methods (section 4.2). The methods that are often employed for calibration are detailed in section 4.3. However, it should be stressed that any of the calibration methods can be employed for FA when only CR information is desired.

The underlying model for multiway FA is the trilinear model. Many methods relax the constraints of the model or expand the types of interactions among the factors; however, the trilinear model still provides the foundation of these methods. The trilinear model is a direct extension of the bilinear model employed in multivariate FA. This model can be presented equivalently in statistical form
(Equation 41): 
\[ \hat{R}_{ijk} = \sum_{n=1}^{N} \hat{x}_n \hat{y}_{nj} \hat{z}_{nk} + E_{ijk} \]  
(41)

or mathematical form (Equation 42): 
\[ \hat{R}_{k} = \sum_{n=1}^{N} \hat{x}_n \hat{z}_{nk} \hat{y}^*_n + E_k \]  
(42)

where \( N \) refers to the number of factors employed by the model to describe the \( I \times J \times K \) data cube, or the rank of the model.

In general, the number and form of factors are not constrained to be representative of any physical reality. With two-way FA, PCA, this is often referred to as the rotational ambiguity of the factors: there is a continuum of factors that satisfy the PCA model and equivalently describe the data.\(^{26}\) However, with three-way analysis, when, for an isolated chemical component (1) the true underlying factor in each of the three modes is independent, except for scale, from the state of the other two modes, (2) the true underlying factor in any of the three modes cannot be expressed by linear combinations of the true underlying factors of other components in the same mode, (3) there is linear additivity of instrumental responses among the species present, and (4) the proper number of factors is chosen for the model, then the factors \( \hat{x} \), \( \hat{y} \), and \( \hat{z} \) are unique and are accurate estimates of the true underlying factors, \( x \), \( y \), and \( z \) (except for a scaling constant). This is shown graphically in Figure 8, where the data set \( \mathbf{R} \) is, in reality, composed of \( N \) triads. If the proper number of factors \( N \) is chosen, the estimates of the factors in each of the triads, \( \hat{x} \), \( \hat{y} \), and \( \hat{z} \), will be accurate estimates of the true underlying factors. In other words, if \( \mathbf{R} \) were formed by a liquid chromatography (LC)/UV/VIS DAS (diode array spectrometer), each \( \hat{x}_n \) would correspond to one of the true \( N \) chromatographic profiles, each \( \hat{y}_n \) to one of the true spectroscopic profiles, and each \( \hat{z}_n \) to the relative concentrations in the \( K \) samples.

4.2 Multiway Factor Analysis

4.2.1 Simple Multiway Principal Component Analysis

A simple manner to attempt multiway principal component analysis (MPCA) is a direct extension of multivariate PCA.\(^{75,76}\) In MPCA, the data cube \( \mathbf{R} \) is unfolded sequentially in each of the three “ways”. This creates three matrices, \( \mathbf{R}_x \), \( \mathbf{R}_y \), and \( \mathbf{R}_z \), where each new matrix has one “way” in common from the original cube. For an \( I \times J \times K \) tensor \( \mathbf{R} \), \( \mathbf{R}_x \) is an \( I \times (JK) \) matrix, \( \mathbf{R}_y \) is a \( J \times (IK) \) matrix, and \( \mathbf{R}_z \) is a \( K \times (IJ) \) matrix. PCA is performed on each of the three matrices. The scores from each unfolding are interpreted as the scores in each way of the cube \( \mathbf{R} \). This philosophy is easily extended to four-way or greater data tensors.

Although this method is fast and simple, it does not create a true three-way model of the data. That is, the data cube \( \mathbf{R} \) cannot be recreated from the collection of scores. The three sets of scores must be interpreted individually. Often these interpretations lead to contradictory conclusions.

4.2.2 Multiway Curve Resolution

Multiway curve resolution (MCR) methods are three-way (or greater) generalizations of the bilinear CR model presented in section 1.2.3.\(^3\). The same ALS algorithms drives MCR as drives CR. The least-squares algorithm cycles through each of the \( N \) ways, successively updating the estimated parameters and applying any constraints assumed on the model. Nonnegativity, unimodality, unique measurements, and closure are commonly assumed to help derive physically meaningful parameters to the model. When the additional constraint

\[ \sum_{n=1}^{N} \hat{x}_n \hat{z}_{nk} \hat{y}^*_n + E_k \]

Figure 8 Construction and decomposition of a three-way array via the trilinear parallel factor analysis (PARAFAC) model.
of “trilinearity” is imposed, MCR becomes an alternative route for solving Equations (41) and (42).

It should be noted that the rigorous model of Equations (41) and (42) is not always appropriate for chemical applications. Kinetic, titration, flow injection, and chromatographic data seldom follow the strict trilinear model. For this reason, MCR allows for only the proper constraints being applied to the model.

4.2.3 Multiway Principal Components Analysis (Tucker Models)

The appropriate model for MPCA is the Tucker3 (T3) model.\(^\text{76–79}\) The trilinear model of Equations (41) and (42) is a specific case of the T3 model. The T3 model is equivalent to the trilinear model. There are only nonzero elements on the super diagonal, then the PCA model the MPCA model is not unique. An appropriate model for MPCA is the Tucker3 (T3) model.\(^\text{76–79}\)

The numbers of factors in each order of the T3 model are constrained to have the same chromatographic profile but different spectral and concentration profiles.\(^\text{80,81}\) If there are the same number of factors in each way, and the model is constrained to have only nonzero elements on the super diagonal, then the T3 model is equivalent to the trilinear model. There are other Tucker models; for example, the Tucker2 model is the two-way analog of the T3 model.

The ALS algorithm for the T3 model (without constraints) yields a least-squares model of the two-way analog of the T3 model.\(^\text{82}\) Like the PCA model the MPCA model is not unique. An infinite number of equivalent rotations of the factors will fit the data.

4.3 Calibration and Prediction

One common method for employing multiway analysis for calibration and prediction is parallel factor analysis (PARAFAC). PARAFAC refers both to the parallel factorization of the data set \(\mathbf{R}\) by Equations (41) and (42) and also to an ALS algorithm for determining \(\mathbf{X}, \mathbf{Y}\), and \(\mathbf{Z}\) in the two equations. The ALS algorithm begins with an initial guess of the \(X\)-way and \(Y\)-way starting profiles. The initial \(Z\)-way profiles are determined by solving Equation (43):

\[
\mathbf{R}_C = \mathbf{A}\mathbf{Z}^T
\]  

such that \(\mathbf{Z} = \mathbf{C}^*\mathbf{R}\) with \(\mathbf{C}^*\) being the generalized inverse of \(\mathbf{C}\) that can be calculated from the normal equations or SVD of \(\mathbf{C}\). In Equation (43), \(\mathbf{R}_C\) is an \(I \times J \times K\) matrix constructed by unfolding the \(K\) slices of \(\mathbf{R}\) in the \(I\) plane where \(R_{i,j,k} = R_{i,j,k}\). Similarly, \(\mathbf{C}\) is an \(I \times J \times N\) matrix formed from the \(N\) columns of \(\mathbf{X}\) and \(\mathbf{Y}\) where \(C_{i,j,k} = X_{i,n}Y_{j,n}\).

Updated estimates of the \(X\)-way and \(Y\)-way profiles are found by solving Equation (44):

\[
\mathbf{R}_A = \mathbf{A}\mathbf{X}^T
\]  

such that \(\mathbf{X} = \mathbf{A}^*\mathbf{R}_A\), and (Equation 45):

\[
\mathbf{R}_B = \mathbf{B}\mathbf{Y}^T
\]  

such that \(\mathbf{Y} = \mathbf{B}^*\mathbf{R}_B\). \(\mathbf{R}_A\) and \(\mathbf{R}_B\) are constructed analogously to \(\mathbf{R}_C\) by unfolding \(\mathbf{R}\) in the \(YZ\) and \(XZ\) planes, respectively. This forms a \(J \times Z \times I\) matrix for \(\mathbf{R}_A\) and an \(X \times Z \times J\) matrix for \(\mathbf{R}_B\). Similarly to \(\mathbf{C}\), \(A_{i,j,k} = Y_{j,n}Z_{k,n}\) and \(B_{i,j,k} = X_{i,n}Z_{k,n}\).

The algorithm proceeds iteratively, cycling through Equations (43), (44), and (45) until the convergence criterion is satisfied. At each step the most recent estimates of \(\mathbf{X}\) and \(\mathbf{Y}\) are used to determine \(\mathbf{Z}\) (or \(\mathbf{Y}\) and \(\mathbf{Z}\) to determine \(\mathbf{X}\), or \(\mathbf{X}\) and \(\mathbf{Z}\) to determine \(\mathbf{Y}\), depending on the equation currently being solved). There are, consequently, two important factors that influence the final estimates of the \(X\)-way, \(Y\)-way, and \(Z\)-way profiles: the starting guess for \(\mathbf{X}\) and \(\mathbf{Y}\), and the convergence criterion.

The PARAFAC algorithm is sensitive to the starting guess of the solution for \(\mathbf{X}\) and \(\mathbf{Y}\). This results from PARAFAC often becoming trapped in local minima and, hence, not converging to the global optimum least-squares solution. Furthermore, the PARAFAC algorithm can become delayed in “swamps” far from the optimum solution.\(^\text{83}\) Consequently, the speed of the algorithm is sensitive to the initial guess for \(\mathbf{X}\) and \(\mathbf{Y}\). The starting

![Figure 9 Construction of a three-way array according to the unconstrained Tucker model.](image-url)
iteration of \( \hat{X} \) and \( \hat{Y} \) can be provided by a random number generator,\(^{64} \) direct trilinear decomposition (DTLD) method,\(^{65} \) or a priori knowledge of analyte profiles. Although this markedly increases the analysis time, when employing a random starting value, multiple initial guesses should be considered. The solution for each starting value will be different; however, if all (or most) of the solutions are similar, it is safe to assume that PARAFAC has converged to near the global optimum solution. The convergence time for PARAFAC can be improved by initializing the algorithm with guesses near the optimum solution. These guesses can come from DTLD or reference spectra of species known (or highly suspected) to be in the data set. Care should be employed when utilizing the DTLD solutions since DTLD often yields significant imaginary components in predicting \( X \)-way and \( Y \)-way factors. The problems caused by initializing PARAFAC with imaginary components can be circumvented by employing the real component of \( \hat{X} \) and \( \hat{Y} \) from DTLD or the absolute value (complex modulus) of \( \hat{X} \) and \( \hat{Y} \) from DTLD.

Two popular convergence criteria for the PARAFAC algorithm are based on changes in the residuals (unmodeled data) between successive iterations and changes in the predicted profiles between successive iterations. In the first case, the algorithm is terminated when the root averages of the squared residuals between successive iterations agree to within an absolute or relative tolerance, say \( 10^{-6} \). Although such fit-based stopping criteria are conceptually easy to visualize, a faster method for determining convergence relies on the correlation between the predicted \( X \)-, \( Y \)-, and \( Z \)-way profiles between successive iterations. When the product of the cosines between successive iterations in the \( X \), \( Y \), and \( Z \) modes approaches arbitrarily close to 1, say within \( 10^{-6} \), the algorithm is terminated. The cosine in the \( X \)-way is defined according to Equation (46):

\[
\cos \theta_X = \frac{x_{\text{old}}x_{\text{new}}}{\sqrt{(x_{\text{old}}x_{\text{old}})(x_{\text{new}}x_{\text{new}})}}
\]

The other two terms, \( \cos \theta_Y \) and \( \cos \theta_Z \), are defined equivalently. Convergence, when \( \cos \theta_X \times \cos \theta_Y \times \cos \theta_Z > 1 - 10^{-6} \), implies that successive iterations in all three modes are correlated to at least \( 1 - 10^{-6} \). Mitchell and Burdick cite, in addition to speed, an additional benefit to correlation based convergence.\(^{63} \) In cases when two factors are highly correlated in one or more of the three ways, ALS methods may become mired in “swamps” where the fit of the model changes slightly but the correlation between the predicted \( X \)-, \( Y \)-, and \( Z \)-ways changes significantly between successive iterations. After many iterations the ALS algorithm will then emerge from the “swamp” and the residuals and estimated profiles will then both rapidly approach the optimum. Hence correlation based convergence is more resistant to inflection points in the error response surface when optimizing the model.

### 4.4 Figures of Merit

In three-way calibration, as with two-way calibration, the figures of merit are similarly derived from the three-way NAS.\(^{6,71} \) Assuming all calculations are performed at unit analyte concentration, the SEL, SEN, and S/N are the magnitude of the NAS divided by the magnitude of the analyte signal, concentration, and noise, respectively. Mathematically, they can be found from Equations (47–49):

\[
\text{SEL} = \frac{\|\text{NAS}\|_F}{\|R_A\|_F} \tag{47}
\]

\[
\text{SEN} = \frac{\|\text{NAS}\|_F}{c} \tag{48}
\]

\[
\text{S/N} = \frac{\|\text{NAS}\|_F}{\|E\|_F} \tag{49}
\]

where \( R_A \) is the response of the analyte at unit concentration, \( c \), \( E \) is a matrix of expected, or estimated, errors, and \( \|\cdot\|_F \) is the Froebus norm (root sum of squared elements) of a matrix. It should be noted that whereas the NAS is a matrix quantity, SEL, SEN, and S/N are all vector quantities. The LOD and limit of quantitation can also be determined via any accepted univariate definition by replacing \( \|\text{NAS}\|_F \) for the analyte signal and \( \|E\|_F \) for the error value.

However, there is still debate over the proper manner to calculate the NAS.\(^{73} \) In the earliest work by Ho et al.,\(^{86} \) the three-way NAS is calculated as the outer product of the multivariate NAS from the resolved \( X \)-way and \( Y \)-way profiles. That is (Equation 50)

\[
x_{\text{NAS}} = x_i^T(I - X_iX_i^T) \tag{50}
\]

and (Equation 51)

\[
y_{\text{NAS}} = y_i^T(I - Y_iY_i^T) \tag{51}
\]

so (Equation 52)

\[
\text{NAS} = xy^T \tag{52}
\]

Similarly, Messick et al. suggested the NAS can be found by orthogonal projection of \( R \) following unfolding each \( I \times J \) sample and interferent matrix into an \( IJ \times 1 \) vector. The three-way NAS is the consequent NAS of Equation (34) refolded into an \( I \times J \) matrix.\(^{87} \) The third alternative, propounded by Wang et al., is to construct the NAS from the outer products of the \( X \)-way and \( Y \)-way
profiles that are unique to the analyte; in this method no
projections are explicitly calculated.\(^{(88)}\)

### 4.5 Batch Analysis

Multiway methods, in particular MPCA, can be employed
to model batch processes.\(^{(89,90)}\) Each historical run of a
batch is treated as a “way” in the data matrix. This
yields a batch \(\times\) time \(\times\) sensors matrix of data. Future
runs are projected on to the factors obtained from three-
way PCA. This yields a condensed data representation of
the process variation that can be employed to construct
SPC charts. The scores from analysis of the historical data
provide confidence limits and control limits. It should be
noted that unlike PARAFAC analysis for calibration of
multiway sensors, there are no true underlying process
“spectra” to be determined. The derived scores and
loading should be interpreted as correlations (see PCA,
section 1.2.1).

### 5 PRETREATMENT OF DATA

The success of multivariate data analysis often depends
on the application of data pretreatment to remove, scale,
or standardize the sources of observed variance.

#### 5.1 Centering and Scaling

“Mean centering” and “variance scaling” are often
performed on multivariate data without much thought
as to the consequences of these actions. Mean centering
removes the average, or mean, response of a given
variable or sample. This translates the variance of the
data set to be centered about the ordinate axis. Variance
scaling normalizes each variable, or sample, such that the
data’s variance becomes unity. This places the data on a
unit sphere. When mean centering and variance scaling
are both applied to a collection of data, the data are said
to be “autoscaled”. Autoscaling places the data on a unit
sphere centered about the origin of the multivariate space
of the data.

There are specific instances when mean centering and
variance scaling should and should not be applied to a
data set. In general, mean centering aids in interpretation
of the FA models and construction of calibrations. By
removing the mean of the data set, often one less factor is
required for analysis. An exception may occur when
the data are collected under “closure”.\(^{(91,92)}\) Closure
exists when the sum of the variables or concentrations
is constrained to equal a preset value. The most
common type of closure is seen in mixture analysis
when the sum of percentage composition of all detectable
species is constrained to equal 100%. Other examples
may occur when improper experimental designs are
employed. When closure exists, mean centering will not
always eliminate a factor. In these instances the errors
introduced by estimating the mean of the data set are
not offset by the gains associated with a more simple
model.

When a data set is variance scaled all variables, or
samples, are given equal weight in determining the factors
of the model. This may be beneficial when variables
with small variance have greater predictive variance than
variables with larger variance. A prime example is seen
in fusing data measurements with drastically different scales (e.g. physical measurements such as temperature
and pressure with spectroscopic data). However, in
most spectroscopic, chromatographic, or electrochemical
analyses, the measurement is chosen so as to be most
sensitive to the analyte of interest. Here, it would not
be favorable to give equal weight to background noise in
uninformative measurements as is given to measurements
with maximum analyte SEN.

A third type of scaling often employed is scaling each
variable or sample to unit area. This scaling is success-
fully applied to samples when matrix or sampling effects
alter the measurement efficiency of a method. Examples
include sample to sample variance due to sample thickness
in NIR reflectance effective path length in other optical
methods. Unit area normalization obscures the abso-
lute concentrations of analytes but preserves the relative
concentration of constituents between and among sam-
ples. Therefore, absolute calibration cannot be performed
unless the calibration set is constrained by closure once
the data are normalized. Unit area scaling is employed in
Lawton and Sylvestre CR (section 3.2.3.2).\(^{(28)}\)

#### 5.2 Background Correction

Background correction methods are often employed in
spectroscopic applications to remove broad features
from the data set. These features hinder calibration as
a large source of variance compared with the analyte
or as a seemingly random source of variance that
consumes many factors in the model. Examples include
fluorescence background in Raman spectroscopy and
scattering backgrounds in NIR reflectance spectroscopy.

Simple efforts at background correction include deriva-
tives, polynomial curve fitting, and Fourier transform
(FT) filtering.\(^{(93)}\) Derivatives remove the portion of a
background that can be modeled by a low-order poly-
ynomial. Taking the first derivative of a spectrum removes
the baseline offset. The second derivative removes the linear
approximation of the background (and the analyte sig-
nal). However, in spite of digital filters for simultaneously
smoothing the data while calculating the derivatives,\(^{(94)}\)
the S/N rapidly declines with each derivatization. Polynomial curve fitting is useful when there are regions of the spectra that contain only background variance. These regions must be distributed across the entire spectrum such that the background can be modeled. FT filtering removes both low- and high-frequency variance across the spectrum. It is assumed that the lowest frequency signal is the background and the highest frequency signal is random instrumental error. Problems may occur with FT filtering due to poorly chosen apodization functions applied to the signal or insufficient ability to distinguish between the signal and the background. This will lead to distortion of the analyte signal.

Multivariate scattering correction (MSC) has been applied with great success to NIR reflectance and transmittance data.\(^{(93,95–97)}\) MSC accounts for the fact that the scattering efficiency of light is a function of wavelength. MSC estimates the amount of scattering in each sample relative to a reference sample. A simple linear model is employed at each wavelength where the scattering background is assumed to have the form (Equation 53)

\[
x_l = a + b\tilde{x}_l + e_l
\]

where \(x_l\) is the NIR measurements for a set of samples at wavelength \(\lambda\) and \(\tilde{x}_l\) is the NIR spectrum of a reference sample at wavelength \(\lambda\). The mean spectrum of the calibration set serves as an excellent reference sample. The additive and multiplicative constants \(a\) and \(b\) are determined by ordinary least-squares regression. Once these two constants are known, the scatter corrected spectra are found in scaled residuals (Equation 54):

\[
x^\text{corrected}_l = \frac{x_l - \hat{a}}{b} = \frac{\tilde{e}_l}{b}
\]

### 5.3 Instrument Standardization

One practical concern with multivariate calibration and prediction is the transport and stability of the calibration models. Ideally, a calibration model can be constructed in the laboratory on a benchtop instrument, then the model can be applied to many similar instruments in the field. Also, once a model has been successfully transported to the field, it will be robust to changes in instrumental SEN and alignment. Of course, the goal of a universally transportable and robust instrument/model has not been achieved. Seemingly identical spectrometers have slight wavelength resolution and SEN differences that can prohibit reliable distribution of the calibration model among numerous instruments. Also, time-dependent instrumental drift eventually can render the calibration model obsolete for whichever instrument the model was constructed.

Individual calibration of each instrument is not an acceptable solution to the problem of model distribution. Calibration may be an expensive, time-consuming task when many calibration samples are needed. The calibration samples are not readily transportable, or the instrument is not easily accessible in the process stream. Concurrently, it is also unacceptable to repeat an entire calibration procedure whenever there are minor changes in the instrumental character.

Instrumental standardization strives to solve the problems derived from instrumental differences when constructing one calibration model for multiple instruments. The instrumental standardization philosophy is to construct the best model possible on one instrument then to build a second model that will transform the spectra from other instruments to appear as if they were recorded on the first instrument. Usually, this transfer function can be reliably calculated with less effort.

One standardization method popular in the literature is piecewise direct standardization (PDS).\(^{(98–101)}\) With PDS, a set of transfer samples are analyzed on both the original instrument and the instrument to which the calibration model will be transferred. It is best if the transfer samples are a subset of the calibration set; however, other surrogate samples may be employed. A separate transfer function is determined for each wavelength in the spectra by least-squares regression using neighboring wavelengths as the independent variables. That is, a local subset of variables measured on the second instrument is employed to build a model that predicts what each measurement would have been if it were measured with the first instrument. This method accounts for shifts and intensity changes over a small spectral window. The drawback of PDS is that success of the standardization is dependent on choice of the transfer samples. The transfer samples must be identical when measured on each instrument and the set of samples must span the space of all encountered spectral changes between the two instruments. Therefore, the choice and number of transfer samples must be optimized by the analyst.

A more useful method of standardization would not require transfer samples to be analyzed. There have been two approaches to this problem. When it can be safely assumed that the only spectral shifts (e.g. wavelength or retention time) occur, a PCA-based method of standardization may be employed.\(^{(102,103)}\) The spectral (or time) indices are shifted such that the projection of each sample into the PC space defined by the original instrument is optimized. A more general method based loosely on MSC has also demonstrated success when there are relatively minor performance differences between the original and second instruments.\(^{(104,105)}\) Here a local selection of wavelengths from each spectrum are regressed against the mean spectrum to build a
transfer function. Consequently, the spectra from the second instrument are not transformed to look like the spectra from the first instrument. Instead, spectra from both instruments are transformed to lie in a common multidimensional space.

6 MODEL VALIDATION (RIGHT VERSUS WRONG MODEL)

One topic that has been alluded to in this article, but not adequately discussed, is the validation of the model. Not only must a decision be made in choosing between linear and nonlinear calibration models, but also the number of factors in the FA and calibration models must be determined. If the chosen model is too simple it will not describe properly the variance in the data set and a systematic bias will become imbedded in the qualitative and quantitative interpretation of the model. If the chosen model is too complex, random noise imbedded in the model will be interpreted as chemically meaningful information. The precision of calibration and estimations with the model will be significantly degraded.

The best method for testing the adequacy of the model is to employ three separate sets of data: a calibration set, a test set, and a validation set. It is assumed that the three sets of data span the same measurement (and concentration) space. All of the models to be constructed are determined from the calibration set. The ability of these models to fit the data and/or estimate the property of interest is determined with the test set. The combination of model and number of factors in the model that performs best on the test set is designated as the right model. Note that by the parsimony principle, if a number of models perform equivalently, the simplest model should be employed. Once the right model has been selected, it is further tested on the validation set. This allows for accurate estimation of the future performance parameters of the model.

The three-data-set method for model construction is designed to guard against “overfitting” of the model to the data. Adding more factors to a model almost always increases the fit of a model to the data set employed to calculate the model parameters. Because the test and validation sets have different realizations of instrumental errors to the calibration set, parameters that model the noise in the calibration set will not precisely model the noise in the other two sets. Estimation of future performance of the model based on the test set yields an overly optimistic estimation of the model’s abilities. After all, that particular model was chosen because it fitted the test set well.

Often it is impractical to collect sufficient data to designate three separate sets for model construction. If only two data sets are employed, the performance of the model on the test set can be estimated by cross-validation (CV). At a pinch, the test set can be eliminated also. However, without a test set it is dangerous to extrapolate the future performance of the model from the calibration set.

CV is a jack-knife method where a number of samples, \( N \), are sequentially left out of the \( I \) sample calibration set. A model is constructed with the remaining \( I - N \) samples and the fit/predictive ability of the model is tested on the \( N \) excluded samples. The \( N \) samples are replaced in the calibration set and this procedure is repeated until all of the \( I \) samples have been excluded in groups of \( N \). The ensemble performance of the models on the excluded data is interpreted as the performance of the model on a true test set would be interpreted.

Process chromatography is an analytical technique which provides for the on-line separation and measurement of the components of a mixture in a chemical process. The chromatographic analyzers utilized for on-line analysis must operate in a continuous and automatic manner, taking a fixed quantity of sample, separating the chemical components using adsorption or partitioning columns, and measuring the concentration of each with a detector. The chromatograph provides both quantitative results, by measuring the area of the peak generated as the components pass through the detector and qualitative results based on the retention time, which is measured from injection to detection.

The most commonly used process chromatographic analyzer is the process gas chromatograph because of its many applications in the hydrocarbon processing industry. A variety of valve, column, and detector configurations are available for these analyses from parts per million to percent levels. All samples must be gas phase or liquids which can be vaporized prior to analysis. The analyzers are controlled using a cyclic timing device which switches valves and columns as the components pass through the system to provide the necessary separation. This time cycle is a limitation of the technique for applications requiring continuous or very fast analysis times. Even with these limitations, the advantages of cost, flexibility, sensitivity, and reliability have made process gas chromatography (PGC) the most widely used analytical technique for on-line process control.

1 INTRODUCTION

Process chromatography appeared on the scene in the mid- to late-1950s. For the first time, we had an analytical technique with the ability to provide a complete compositional analysis, yet one that was simple in principle and application, and broad in scope and analytical power.

Development of the chromatographic analyzer and its use for process measurement and control has increased at a phenomenal rate over the past 50 years. Uses of the chromatographic analyzer range from the simple monitoring of one component in ambient air to providing a computerized output for 50–100 components in a complex mixture. Today there are literally thousands of these analyzers being used, yet there are few references to their applications. This is primarily due to the proprietary nature of many of the chemical processes where these analyzers are being utilized.\(^1\)

Basically, a process chromatograph resembles its laboratory counterpart more closely than most other plant analyzers. The primary differences result from requirements imposed by the plant environment, safety, and
automatic operation. The process analyzer may be considered as having two distinct sections: the analyzer section (where the analysis actually takes place) and the control section or data system (which generates and reduces the data, sends them to the control computer, and provides maintenance functions). The analyzer will automatically take its own sample, separate the components of interest and provide a detector signal output proportional to their concentrations. These signals are then processed in the control section and sent to a recording device or a process control computer. The analyzer will continue to repeat the same cycle, which lasts from a few seconds to several minutes, 24 h per day and 365 days per year until it is interrupted for calibration or maintenance.

2 HISTORY

Chromatography began at the turn of the century when Ramsey separated mixtures of gases and vapors on adsorbent materials. Later a Russian botanist, Michael Tswett, separated plant pigments by passing a liquid mixture through a column of solid adsorbent material. The term “chromatography” is identified with this work published by Tswett in 1906. In this publication he described how brilliant bands of color were produced when a mixture of plant pigment and solvent passed through the column. Based on his findings, he coined the term from the Greek words “chromo”, which means color, and “graph”, which means writing, to describe the scientific process as color writing. This paper has been translated in English and republished because of its scientific importance to the field.

Based on the same principles, gas chromatography (GC) evolved, which utilized a gas as the mobile phase. It is usually identified with American chemist, D.T. Day, who performed experiments with crude petroleum fractions and separated many of its components by passing it through a column filled with Fuller’s earth. The important seminal work was first published in 1952 by Martin and his co-worker James acted on a suggestion made 11 years earlier by Martin himself in a Nobel Prize-winning paper on partition chromatography. This publication described the use of a gas instead of a liquid as a mobile phase and the results were presented at the Analytical Chemistry Congress at Oxford in 1952. It was quickly recognized that GC was simple, fast, and applicable to the separation and measurement of many volatile chemical components, especially petrochemicals, for which distillation was the method of choice for separation at that time. Theories describing the technique were tested and led to still more advanced theories and understanding. Almost immediately the demand for analyzers incorporating the technique gave rise to a new industry that responded quickly by developing commercially available laboratory gas chromatographs.

Essentially simultaneous with the development of gas chromatographs for this use, a similar form of analyzer was developed for industrial applications. An instrument for PGC first appeared in the mid-1950s as a result of work done by the Union Carbide Corporation in South Charleston, WV, USA. Because they were not interested in the actual manufacture of such a product for the commercial market, the concepts were transferred to a small display and control panel manufacturer, Watts Manufacturing, of Ronceverte, WV, USA. This company first manufactured the product on a contract basis for Union Carbide, followed by manufacturing and distribution on a global basis for the hydrocarbon processing industry. In 1957, Beckman Instruments acquired the company and transferred the manufacturing to California. Several of the technical people who elected not to move to California formed a second company known as Greenbrier Instruments. These two companies led the introduction of PGC to its worldwide adaptation as we know it. Today, PGC is the most widely used multi-component process analysis techniques. For this reason, GC will be the primary emphasis of this article. It is a mature technique and a very important one for process monitoring and control. The worldwide market for PGC analyzers is estimated to be about $100 million or over 2000 analyzers annually.

3 DEFINITIONS

To understand better the basis of this technology, definitions of chromatography, GC, and PGC will be introduced.

3.1 Chromatography

Chromatography is defined as a technique for the separation of components in a mixture. Both qualitative and quantitative measurements are possible with this technique; however, in process analyzers, the quantitative aspects of the application predominate.

Basically, chromatography consists of a two-phase system. One phase is stationary, or static, and consists of the separating media. The second phase is mobile and serves to move the sample being analyzed over or through the separating media. Chromatography can be classified according to the type of moving phase and the static phase, e.g. gas–solid chromatography or liquid–solid chromatography. This describes the chromatographic process according to the physical state of the mobile
phase. Thus, in GC the mobile phase is a gas, and in liquid chromatography (LC) the mobile phase is a liquid.

3.2 Gas Chromatography
In GC, the separating media are contained in columns and consist either of a solid adsorbent material (gas–solid chromatography) or of a liquid held by a solid (gas–LC). The mobile phase consists of a gas which pushes or carries the gaseous sample through the column. The separation of the components in the sample results from a difference in the forces by which the column materials tend to hold or retain each of the sample components. Whether the nature of these forces is adsorption, solubility, chemical bonding, polarity, or molecular filtration, they retain some components longer than others. Consequently, all components pass through the column at varying speeds and emerge in inverse order of their affinity for the stationary column materials.

Normally, the components tend to separate according to their boiling points or vapor pressure, with the low-boiling, high-vapor-pressure components emerging first. However, other physical or chemical properties also play a part in the separation, and it is possible to affect the separation of components whose boiling points or vapor pressures differ only slightly or not at all using properties such as polarity, molecular size, or chemical interactions.

3.3 Process Gas Chromatography
A process gas chromatograph is an analyzer which has been designed for installation and operation on-line with a chemical process. The analyzer will continuously and automatically analyze a flowing process stream in a cyclic, repetitive manner to determine the chemical composition of the flowing process stream. The primary purpose of locating the analyzer on-line or adjacent to the chemical process is to obtain the analytical results with a speed of response that is comparable to process changes. This information will, in turn, be used for process monitoring and control. In general, such an analyzer is designed with the columns, valves, and detectors to perform a particular analysis on a single stream, or at most, a few liquid or gas streams of similar composition. The typical analyzer is designed to measure only key components necessary for process control in the stream. The cyclic nature of analysis which ranges from a few seconds to minutes is viewed by many as a limitation of the technique.

4 MEASUREMENT PRINCIPLES
As a method for separating and measuring the individual components of a complex mixture, GC is unequaled. A qualitative description of the separation process is as simple as is the essential apparatus. An understanding of the separation process is critical for a real appreciation of the power and scope of the technique. More specifically, a description of the processes going on in the separating column, the heart of any chromatographic system, is important to understanding the operation of a gas chromatograph.

For gas–LC, a separation column is prepared using a small-diameter tube (ranging from 0.7 to 4 mm internal diameter) which is packed with inert solid particles coated with up to 20 wt.% of a nonvolatile liquid phase.

The support for the liquid phase can also be the walls of the tube, in which case the tubing diameter will be in the capillary range of micrometers (typically sizes are 100, 250, 320 and 500 µm). The moving phase consists of an inert carrier-gas (N₂, H₂, He) flowing through the column. Into this moving stream is injected the sample mixture, the components of which are in equilibrium in characteristic ratios between the gas and liquid phases. In essence, components more soluble in the liquid move more slowly through the column and a detector at the exit will measure the components as they emerge as a series of peaks. The retention time or time it takes for each component from injection to elution from the column is the qualitative characteristic, whereas the area under the peak is a quantitative measure of its concentration. A chromatogram of a mixture is shown in Figure 1.

There has been a great deal of theory developed about gas–liquid partition principles. Fundamental to the principle is the fact that a given component partitions itself between the gas and liquid phases in a definite ratio. This partition ratio of a component \(i\) is illustrated in Figure 2, and given by Equation (1):

\[
k_i = \frac{K_i V_l}{V_m}
\]

where \(K_i\) is the partition coefficient and \(V_l\) is the liquid volume in the column and \(V_m\) is the gas volume. The value of \(k_i\) can vary according to the ratio \(V_l/V_m\).

![Figure 1 A typical chromatogram.](image-url)
Figure 2 Partitioning between gas and liquid phases.

One can measure $k_i$ from the information illustrated in Figure 3 (using Equation 2) for the partition ratio:

$$k_i = \frac{t_R - t_0}{t_0}$$  \hspace{1cm} (2)

The peak $t_0$ is the retention time of the air peak, which represents the retention of a non-absorbed gas.

The efficiency of a column is measured by using a concept from distillation theory; the total number of theoretical plates, $N$, or average plate height, $H$, which is $L/N$, where $L$ is the column length. In Figure 4 this is given by the equation for efficiency (Equation 3):

$$N = 16 \left( \frac{t_R}{w_b} \right)^2$$  \hspace{1cm} (3)

where $t_R$ is the retention time from sample inject and $w_b$ is the width of the base of the peak as shown in Figure 4.

Figure 3 Partition ratio.

This provides a measure of efficiency by showing how much the peak broadens as it moves through the column.

Another parameter often measured is the separation or resolution produced between two components, 1 and 2. This is measured by using the data in Figure 5 applied to the equation for resolution (Equation 4):

$$R = \frac{\Delta t}{\frac{1}{2}(w_1 + w_2)}$$  \hspace{1cm} (4)

A resolution of 1 means that two adjacent peaks are just separated at their bases. These three equations allow us to determine the performance of a chromatographic system under different conditions.

The plate theory and its associated equations as presented above provide us with a method to measure column performance. A different theoretical treatment is necessary to understand the experimental factors that affect column performance. To evaluate the reasons for peak broadening under the realistic conditions of column operation, Van Deemter(13) developed a well-known equation which is useful in its simplified form (Equation 5):

$$H = A + \frac{B}{u} + Cu$$  \hspace{1cm} (5)

where $A$, $B$ and $C$ are constants containing terms related to the factors shown in Figure 6, $H$ is the measured plate height, and $u$ is the carrier linear gas velocity.

From a qualitative perspective, this equation tells us a lot about the behavior of the chromatographic system. The $A$ term is a measure of peak broadening resulting from molecules going down unequal paths in the column. It can be minimized by maintaining uniform particles and packing density in the column. The $B$ term represents the peak broadening caused by molecules diffusing longitudinally along the column length. This effect can be minimized by the choice of carrier and flow rate of the carrier, but we must consider the $C$ term in this region. The $C$ term measures band broadening resulting from the time required to reach equilibrium between the gas and liquid phase, and is a measure of resistance to mass transfer.

The above factors for $A$, $B$, and $C$ are a generalized way of looking at column performance under different...
operating conditions. For a more complete understanding of the mechanisms involved, we can refer to complete treatment by Giddings.\(^{(12)}\)

We now have some understanding of the manner and direction in which variable factors influence the performance of chromatographic columns and methods of measuring their performance. This knowledge is very useful in the design and operation of process gas chromatographs for the wide range of applications for which they are employed.

5 LABORATORY VERSUS PROCESS

PGC is defined as an industrial GC method that can be carried out on an automatic, repetitive basis for the purpose of controlling process streams. Although analytical chemists agree that the principles for a gas chromatograph are the same for laboratory and process analyzers, the requirements and, therefore, the analyzers differ considerably. Although in principle laboratory analyzers can be adopted for on-line use, special process analyzers are almost always used. Because they are operated continuously and with little attention from operators, process gas chromatographs must meet higher standards of reliability.

Process gas chromatographs are expected to provide long, accurate, trouble-free service with minimum maintenance—a difficult task considering the relatively complicated hardware and harsh operating environment. The hardware should be constructed such that when maintenance is required it can be performed quickly and easily. A large number of chemical plants using process gas chromatographs are operated under rigid safety rules requiring protection from corrosive and flammable process materials. Provisions must be made for operation in a relatively unprotected plant environment. The typical process gas chromatograph is designed and the valves, columns, and detectors are configured for one specific analysis from one or more process stream with similar chemical composition.

An important requirement of a process gas chromatograph is that it provides meaningful data in the simplest manner possible. The routine presentation of data of a conventional laboratory gas chromatograph is not practical for a process gas chromatograph. To provide the required data the typical readout system for a process gas chromatograph consists of a bar graph, trend, or digital signal presentation (Figure 7).

[Figure 6 Van Deemter plot. (Reproduced by permission from Dr H.M. McNair, Virginia Polytechnical Institute and State University, Blacksburg, VA, USA.)]

[Figure 7 Bargraph trend and digital outputs.]
Some unique features of a process gas chromatograph include:

1. a constantly fresh sample since the analyzer is connected directly to the process stream;
2. faster analysis times;
3. multiple columns and valves;
4. less manpower required for operation;
5. results immediately available to the process operator;
6. can be incorporated into closed-loop control;
7. isothermal operation is most common;
8. designed for operation in hazardous environments.

6 BASIC HARDWARE COMPONENTS OF A PROCESS GAS CHROMATOGRAPH

The analyzer one utilizes in a chemical plant will necessarily have fundamental differences from one in the laboratory employing the same principles. The plant environment will require a rugged and usually explosion-proof or air-purged design. The analyzer will obtain its own sample, analyze it, process the information coming from the detector into useful information, and output the data to a recorder, printer, or computer. It must continuously repeat the same cycle to provide analytical results needed for precise process control. Because of the importance of this feature, the automatic performance and reliability of a process gas chromatograph must be very high.

A process gas chromatograph may be thought of as being divided into two sections, an analyzer section and controller or programmer section. These two sections will be presented in detail, starting with the analyzer (Figure 8).

6.1 Analyzer Section

The analyzer section contains the basic hardware components such as sample valves, columns, column switching valves, and detectors, enclosed in a precisely temperature-controlled oven. This section is usually explosion-proof or air-purged to meet the requirements of a hazardous area. In certain applications or designs it may be necessary to locate pneumatic components in the oven to eliminate variances caused by ambient temperature changes.

6.2 Oven

The typical process gas chromatograph employs a single, isothermal temperature zone. Three basic designs have been used, the air bath oven, airless oven which uses resistive heating elements, and the explosion-proof bell-jar design. The most common is the air-bath oven which incorporates an explosion-proof heater and detector in a non-explosion-proof air bath enclosure. Using dilution purging, these ovens meet the requirements for location in hazardous areas, i.e. Division 1 or Zone 1.

With the air-bath design, 2–3 standard cubic feet min\(^{-1}\) or 1.0–1.5 standard Ls\(^{-1}\) of air is passed through an electrical heating element. This oven’s design is capable of operating at temperatures from 50 to 200°C with a stability of ±0.1°C or better.

Although isothermal operation is the most common, temperature-programmed ovens are available for special applications involving a wide boiling-point range of chemical components. These temperature-programmed designs normally provide isothermal temperature control for sample injection valves and the detector, with only the column being temperature-programmed. This is accomplished using a small temperature-programmed oven within the isothermal oven. This oven-within-oven design provides the speed and precise temperature programming necessary for process control (Figure 9). Another feature utilized to reduce the time required to cool the programmed oven to its initial temperature is a vortex cooler that pumps cool air into the oven following a program to the final temperature. The design of a temperature-programmed oven requires special precautions to ensure that it meets the hazardous area requirements.

6.3 Carrier-gas

Basic to the efficient operation of a process gas chromatograph is the quality of the carrier-gas and other support gases. The carrier-gas must be free of hydrocarbon impurities and moisture for proper operation. Often impure carrier-gases are responsible for reducing the normal useful life of the column system used for specific applications. In many countries it is difficult, if not impossible, to obtain gases of sufficient quality to allow proper
operation of the gas chromatograph. This limitation can be overcome to some extent by using cleanup systems such as traps and catalytic converters. These systems are helpful but must be properly maintained to ensure long-term operation.

The type of carrier-gas used for a specific application is normally detector dependent. The thermal conductivity detector (TCD) uses either hydrogen or helium as the carrier-gas. For the flame ionization detector (FID) the carrier-gas most commonly used is nitrogen. Other factors which dictate the choice of carrier-gas include safety issues, cost, speed, availability, purity, and the components being measured.

6.4 Sample and Column Switching Valves

Process gas chromatograph valves are uniquely designed to introduce reliably a fixed volume of gas or liquid sample into the carrier-gas stream and to switch columns into various positions in the carrier-gas stream, while introducing minimum void volume into the system.

Numerous types of valves have been used, but the most common are the sliding plate, diaphragm, rotary, and liquid-injection sample valves. For gases an external sample loop is used to control the volume of sample injected. With liquid samples the volume of sample is metered with an internal hole or channel in the valve slider of the stem. The volume of sample injected in either case is dependent on the sensitivity necessary for the application, but is typically milliliters for gases and microliters for liquids.

The choice of sample valve is a critical element in every application, since it must be compatible with the sample and operate reliably at the operating temperature necessary to perform the application. These valves are available in corrosion-resistant materials such as Hastelloy™, Monel™, and Teflon™. The liquid injection valve design permits injection of the liquid sample through the wall of the analyzer from the ambient outside temperature to the heated interior where the sample is flash vaporized by a temperature-controlled vaporizing zone prior to being transported to the column by the carrier-gas. This is particularly beneficial for liquids with low-boiling components (such as butanes), which will vaporize when exposed to the oven temperatures. This partial vaporization of the liquid sample will result in nonrepeatable sample volumes and subsequent errors in the measurement.

In addition to injecting samples, the various types of valves described are also used for column switching. The primary reason for column switching, sometimes called multidimensional chromatography, with process gas chromatographs is to obtain a speed of response necessary for optimum control of the process being controlled. Other reasons include:

1. All components in the sample must be quantitatively accounted for and removed from the column system in each cycle. Components which are not eluted will accumulate and change the characteristics of the column or elute with a subsequent analysis and interfere with a measurement.
2. The column separation must be designed for upset conditions which may occur in the process in addition to normal conditions.
3. Columns must be protected from components which are irreversibly or strongly absorbed.

Because of these design requirements, process column design has greater emphasis on multicolumn, multivalve switching techniques. While there are literally hundreds of possible column configurations, there are a few basic concepts which are used in combination with all these configurations. These configurations and how they are used are described in the following examples.

6.4.1 Backflush to Measure or to Vent

This is the most widely used technique, appearing as a part of every column application. It consists of two columns, a backflush column and an analytical column in series, with provision for backflushing the first or backflush column to vent while providing carrier-gas to the analytical column during the backflushing operation.

The backflush column makes a partial separation and is then backflushed, rejecting any unmeasured components. The remaining components are separated in the analytical column prior to passing into the detector.
In general, the use of backflushing is good housekeeping practice; it ensures that unknown heavy components are removed from the column system in each cycle, preventing interference in later cycles.

The backflush to measure configuration is similar except that the backflush column is backflushed to the detector, permitting measurement of all the components remaining in the column. A typical application utilizing this technique is the measurement of British thermal units (BTU) or heating value, where the C₆₊ fraction is backflushed to measure.

### 6.4.2 Dual Column

In this configuration a valve may be used to switch columns so that the components eluted from the first column are passed either into a second column for storage and further separation or directly into the detector. A typical example involves the separation of light or fixed gases, O₂, N₂, CO, and CH₄, on a dual column, such as 5 Å molecular sieves, which is a commonly used gas–solid column packing material.

### 6.4.3 Heart Cut

This configuration is used most frequently for trace analysis with an FID. The application involves the measurement of trace components on the trailing edge of a major component such as trace acetylene in an ethylene product stream. Two columns are arranged to allow narrow cuts of sample from the first column to be taken into the second column, the bulk of the sample being discarded to vent. The trace component plus the tail of the major component are separated on the second column. The second column only has to separate the trace component from a few percent of the major component instead of the 90+% necessary without a venting or heart cut of the major component.

### 6.4.4 Selector or Foreflush Valve

This configuration provides the ability to select from two parallel column systems, wherein one at a time will be directed to the detector. This will allow two different types of columns to be used for separation of different fractions of the sample. This configuration may also be used to select between two different detectors to provide the sensitivity necessary to measure different fractions of the sample.²

There are other configurations of column switching which have been used over the years, but the above are the most common, and a basic understanding of these will encompass the majority of applications.

The valves used for column switching are the same as those used for sample injection, with the exception of the liquid sample injection valve. These include the sliding plate, rotary, and diaphragm designs. The sliding plate and rotary valves are similar in concept (Figure 10). They utilize a drilled or grooved surface slider or rotor, which is actuated from one position to another, either in a linear or rotary motion, along the finely machined surface of a metal plate or housing. The grooves in the surface connect the valve ports that have been machined in the metal plate. In each position the ports are connected in a different configuration. This provides two different flow paths for the carrier-gas through the valve to allow the valve to perform one of the functions described.

![Figure 10 Sliding plate and rotary sample valves. (Reproduced by permission. © Copyright Instrument Society of America. All rights reserved.)](image-url)
Typically, springs are used to press the slider or rotor against the plate. A wide variety of construction materials are available for the slider, rotors, and plates to meet the special requirements of an application based on corrosiveness, pressure, and temperature. Normally air pressure is used to switch the valve between positions.

A different concept is used in design of the diaphragm valve (Figure 11). Instead of a single surface moving against another as used in the rotary or sliding plate design to change the direction of flow of the carrier-gas through the various ports, sets of rods push against a flexible diaphragm to open and close alternating ports. This design is also spring loaded to maintain the tension needed to seal the ports being switched. As with the sliding plate and rotary valves, air is used to actuate the valve or to switch from one position to another. This type of valve is recognized for its fast switching time and low dead volume.

The liquid injection valve or syringe valve is ideally suited for the injection and vaporization of liquid sample for PGC (Figure 12). The valve is mounted through the oven wall with the actuator and sample chamber external to the oven. The vaporizing chamber and carrier connection are located inside the oven. Sample flows through the sample chamber and fills a groove cut around the circumference of the valve stem. This groove provides for a fixed volume of sample ranging from 0.25 to 10 µl. The valve is actuated by an air-driven piston which pushes the stem into a vaporizer where the sample is flash vaporized and carrier-gas transports the sample to the column for separation. The operation of the valve is analogous to syringe injection with a laboratory chromatograph where a fixed volume of sample is injected through a septum into a vaporizer and transported into the column by the carrier-gas.

Each of the valves described has advantages and disadvantages, depending on the application in which they are used. The most important criteria for the selection of one valve over another are reliability and ease of maintenance. Since the sample-injection and column-switching valves are essentially the only moving, mechanical parts of the process gas chromatograph, they are at the top of the list of parts most likely to fail. For this reason, a great deal of effort has gone into the design of the valves over the years since PGC was introduced.

6.5 Columns

For many years, packed columns were the only type of columns used for PGC. With evolving demands requiring faster, more complex separations, capillary columns are replacing packed columns for many applications. Because capillary columns are much more efficient, that is, they have more theoretical plates per unit length, they provide simplified separations and faster analysis times. Capillary columns are especially advantageous for high-molecular-weight samples which are liquids at ambient temperature. Lighter gas-phase sample separations are still more easily performed with packed columns. The use of capillary columns in PGC also dictates a change in the design of the hardware components. The dead volume in valves and detectors must be minimized to take advantage of the efficiency gained using these columns.

6.5.1 Packed Columns

Typical column diameters for PGC applications are 1/8, 3/16, or 1/4 in (2, 3, or 4 mm) internal diameter, with 1/16 in (0.7 mm) internal diameter being used in special high-speed applications. The length of the column depends on the difficulty of the application and selectivity of the packing material for components being measured. The packed column length seldom exceeds 20 ft (6 m) because of the pressure drop across the column. With large pressure drops it is difficult to obtain the optimum flow rate through the column, resulting in peak broadening and reduced sensitivity. The packing material used in the column is either an absorbent (gas–solid chromatography) or a partitioning material (gas–LC). In the case of adsorbent packings such as
Porapaks, molecular sieves and Durapaks, they are used as purchased with a particular mesh range or particle size (80–100 or 100–120 mesh are most common). For partitioning columns, a stationary liquid phase is coated on a solid support with a large surface area. The weight percent of liquid phase coated on the solid support may be varied to enhance the separation (20 wt.% is the maximum). The solid support is normally 80–100 or 100–120 mesh for 1/8 in (2 mm) internal diameter columns. These packing materials may be purchased with the liquid stationary phase already coated on the solid support. In fact, most users of process gas chromatographs purchase identical prepacked columns as replacements for existing columns. This eliminates or reduces to a minimum the method development step.

6.5.2 Capillary Columns

As the demands on the process gas chromatograph increase relative to speed of analysis, trace measurement, complexity of sample, and component resolution, the inherent advantages of capillary columns become very important. There is a general feeling that capillaries are more producible, expensive, fragile, and difficult if not impossible to work with. The current switch of interest to this type of column for process applications is the result of two significant developments, as follows.

The development of commercially available surface-bonded columns has extended column lifetimes and reduced associated problems with column bleeding. The second development involves the elimination of the mechanical instability problem. The reactivity of metal capillaries and mechanical instability of glass capillaries have been overcome by the introduction of fused-silica columns. Because fused silica has a much higher degree of cross-linking within the silicon–oxygen matrix than ordinary glass, it enjoys a higher tensile strength and permits the construction of thin-walled flexible columns. To protect against surface corrosion, several coatings of a polyimide are applied to the outer wall of the flexible fused-silica column. Most recently, silica-coated steel capillary tubing has become commercially available and the further enhanced mechanical stability has led to the replacement of many fused-silica columns for PGC applications.

Commonly capillaries of 0.25 mm internal diameter and varying lengths (30 m is most common) are used; smaller internal diameters have been used for faster analysis. The introduction of megabore (0.35–0.50 mm) columns allows their use as replacements for packed columns with minimum hardware changes being required. These columns provide higher efficiencies than packed columns using the same stationary phase. Better separation is achieved since longer lengths can be used (because of high permeability).

6.6 Detectors

After a chromatographic column has separated the components in the sample, they pass into the detector, where they are measured. If the chromatographic system has been properly designed, the electronic output from the detector will be proportional to the concentration of the component. Several different types of detectors have been developed, but those most commonly used can be separated into two categories: concentration and mass flow rate. This classification system distinguishes between those detectors which measure the concentration of the sample in the carrier-gas and those which directly measure the absolute amount of sample irrespective of the volume of carrier-gas. Examples of concentration-type detectors would be the TCD and electron capture detector, while the FID is a mass flow rate type. One consequence of this difference is that the peak areas and peak heights are affected by changes in carrier-gas flow rate.

To understand better the reasons for this difference in detector types, consider the effect on a TCD signal if the flow is completely stopped. The detector cell remains filled with a given concentration of sample and its thermal conductivity continues to be measured at a constant level. However, for a mass flow rate detector such as the FID, in which the signal is generated from the ionization process in the burning flame, complete cessation in the flow rate will cause the delivery of sample to the detector to stop and the signal will drop to zero. Consequently, the quantitative results acquired at different flow rates will be affected. This affect emphasizes the need for well-controlled flow rates through the chromatograph to ensure repeatable results.

The chromatogram produced by a detector consists of a series of peaks, each of which corresponds to a different component as it passes through the detector. The area under each peak is proportional to the total mass of that component. Hence the chromatographer may calculate weight percent compositions from area ratios represented by the chromatogram. With the TCD, the peak area is inversely proportional to carrier-gas flow rate, so the flow rate must be kept constant for accurate quantitative analysis. For detectors responding to mass flow rate, such as the FID, the peak area is independent of carrier-gas flow rate.

Generally, the usefulness of a detector, regardless of the type, may be evaluated in terms of the following characteristics:

1. selectivity
2. sensitivity
3. response
4. noise
5. linear range.
Secondary to these aspects for PGC, it is important that the detector of choice is simple, rugged, and insensitive to minor changes in flow rate and temperature.

The most common detector types used for PGC applications are the TCD, because of its universal response, the FID, because of its sensitivity to organic components, and the flame photometric detector, because of its selective response to trace levels of sulfur components. Numerous other detectors have been used because of their specificity towards certain components, but their applications are very few. The three most commonly used detectors will be reviewed relative to their operation, advantages, and limitations.

6.6.1 Flame Ionization Detector

The FID is probably the most popular detector used for PGC because of its wide dynamic range ($10^7$) and sensitivity to trace-level components (parts per billion levels of many organic components). Current designs of this detector exhibit extremely low dead volumes, making them ideally suited for capillary column applications.

The gas chromatograph column effluent flows into an oxygen-rich hydrogen flame where the combustible components are burned, producing fragment ions. The ions produced are subjected to an electrical field produced by two electrodes, the jet itself acting as one electrode and the other as the collector. A potential of 150–300 V is applied across the electrodes, one negative and the other positive. The ionic species produced in the flame provide a source for current flow between the electrodes. The current flow is directly proportional to the concentration of ions produced, which, in turn, is proportional to concentration of the component in the column effluent. The hydrogen fuel and column effluent are mixed and pass through the jet. A surrounding flow of air is provided to support combustion. The detector response is dependent on the flow rate of the carrier, air, and hydrogen, the flow rate of hydrogen being the most critical. Typical flow rates used are 30 mL min$^{-1}$ of carrier, 30–40 mL min$^{-1}$ of hydrogen, and 300 mL min$^{-1}$ of air (Figure 13).

![Figure 13 An FID. (Reproduced by permission from Dr H.M. McNair, Virginia Polytechnical Institute and State University, Blacksburg, VA, USA.)](image)

The FID is essentially nonresponsive to the components of combustion, inert gases, and inorganic compounds. It is highly responsive to organic components, the level of which depends on the number of carbon atoms and the other molecules to which they are bonded. For simple molecules there is essentially a one-to-one relationship between the number of carbon atoms and the response. For more complex molecules containing oxygen, halogens, nitrogen, and sulfur atoms, in addition to the level of saturation within the sample molecule there is a corresponding effect on the flame response. For this reason it is necessary to calibrate the FID for each component being measured.

The list of components which cannot be directly measured with an FID includes H$_2$O, NH$_3$, CO, CO$_2$, COS, CS$_2$, SO$_2$, H$_2$S, and the inert gases. In the case of CO and CO$_2$, a catalytic conversion with hydrogen and a nickel catalyst at 400–450°C produces methane, which can be measured with the FID.

Although the FID is considered to be a very sensitive detector, its efficiency as an ionization source is limited. A very small percentage of molecules passing through the flame are actually ionized and the high sensitivity possible is a result of its very low noise level ($10^{-13}$–$10^{-14}$ A) of the output. This low noise level allows high-gain electrometers to be used to amplify the current output generated by the ionization process.

The purity of the air being used is critical for proper operation of the FID. Any traces of hydrocarbons, moisture, or particles that pass into the flame will result in a noisy output. If it is necessary to use plant or instrument air, an air cleanup oxidation catalyst should be used.$^{(10)}$

A unique feature often incorporated in a process FID is a flame-out sensor. The sensor is normally a thermocouple which senses the flame temperature and provides a signal to the associated electronics when the flame is extinguished. In the event that there is a flame-out, an automatic ignition circuit is energized which provides a current through an ignition coil, resulting in reignition of the flame. Such circuits may be designed to limit the length of time the ignitor is energized because of safety considerations.

6.6.2 Thermal Conductivity Detector

The TCD is a concentration-sensitive detector with moderate sensitivity (low parts per million) and a dynamic range of $10^4$. The TCD measures the rate at which heat is conducted away from a hot body. The rate of heat loss depends on the composition of the surrounding gas. This composition varies as the components pass through the detector from pure carrier, to carrier plus sample, to pure carrier. This transition results in a peak being recorded as the output from the detector.
The TCD exhibits a universal response and is inexpensive, rugged, and simple compared with other detector types. The basic design of the TCD consists of a large mass, metal block made from steel or aluminum. Holes are drilled in the metal block to mount the filaments or thermistors. A carrier flow path with one of three designs (diffusion, semidiffusion, or flow-through) is made in the block to allow the carrier to pass by the filament or thermistor. The filament is a metal coil with a large resistance to temperature coefficient, such as tungsten or tungsten and rhenium alloy, and the thermistors are metal oxides. The filaments are electrically connected in a simple Wheatstone bridge arrangement as shown in Figure 14. Sample plus carrier flow through one side of the detector, called the sample side, and the other side of the detector is the reference side, with carrier-gas only.

An electric current is passed through the filaments, causing them to be heated to a constant temperature depending on the amount of current supplied, the thermal conductivity of the carrier-gas, and the temperature of the thermal conductivity block. With only carrier-gas flowing through the sample and reference sides of the detector, the Wheatstone bridge is balanced and the detector signal is at a minimum. As a component elutes from the column and passes the detector the filament begins to heat up, and the resistance changes because the carrier plus sample has a lower thermal conductivity than the pure carrier. As a result of the change in resistance the Wheatstone bridge is unbalanced and a signal is recorded. For maximum sensitivity a carrier-gas with high thermal conductivity such as hydrogen or helium is selected. Other factors affecting sensitivity are the current through the filaments and temperature of the TCD block. As the current supplied to the filaments is increased, the sensitivity is increased, and unfortunately this also results in shorter filament life. The detector block temperature should be maintained as low as possible, to maintain the maximum differential in temperature between filament and block for maximum sensitivity.

The TCD is one of the most popular detectors for PGC because of its universal response. This detector senses any component other than the carrier-gas that passes over the filaments. Consequently, many components which cannot be measured with an FID are possible with a thermal conductivity design.

The primary limitation is the sensitivity, typically in the tens to hundreds of parts per million range, depending on the component being measured. Many attempts have been made to enhance this sensitivity because of the many other favorable attributes (simple, rugged, inexpensive) of this detector. In fact, it has been suggested that for low volume flow rates and small sample sizes required with very fast chromatography, the TCD response will surpass that available from the FID.

### 6.6.3 Flame Photometric Detector

The flame photometric detector is used in PGC specifically for applications involving trace-level sulfur-containing compounds. Similarly to the FID, it uses a hydrogen flame to burn the sample as it elutes from the column. Unlike the FID, the flame is hydrogen-rich (reducing atmosphere) for the flame photometric detector. Instead of measuring the current flow produced by an ionization process, the flame photometric detector measures the light emitted when the sulfur compound is burned. The emission intensity of specific wavelengths, characteristic of sulfur-containing molecules, is selected using a fixed filter (394 nm) and passes into a photomultiplier tube where the signal is measured and a voltage output proportional to the concentration is generated.

As the sulfur-containing compound is burned in the flame, excited-state $S_2^+$ molecules are formed. As these molecules return to the ground state they give up energy in the form of light of a specific wavelength which may be measured with the photomultiplier tube. The detector has a very high sensitivity (parts per million or billion) for small sulfur-containing molecules such as $\text{H}_2\text{S}$, COS, CS$_2$, SO$_2$, CH$_3$SH, and C$_2$H$_5$SH. This unique, specific sensitivity for sulfur-containing molecules make the detector ideal for measuring trace levels in natural gas, ethylene, propylene, emissions, and other hydrocarbon-rich streams. Because of the high level of sensitivity it is critical that the support gases used, such as carrier, hydrogen, and air, are also of high purity. The complete chromatographic system must be clean to avoid high background interference and detector noise which results in a loss of detector sensitivity. The signal being measured is nonlinear, based on the formation of the $S_2$ molecule, which requires special handling of output signal. Either a calibration curve must be generated or

![Figure 14 Wheatstone bridge of a TCD. Filaments 1 and 2 are reference filaments. (Reproduced by permission from Dr H.M. McNair, Virginia Polytechnical Institute and State University, Blacksburg, VA, USA.)](image-url)
a linearizing circuit must be built into the electronics. Although special precautions must be taken to ensure optimum performance of this detector, it is unique in its ability to measure trace levels of sulfur compounds in a hydrocarbon background. In many situations the purpose for this measurement is the protection of a very expensive catalyst, making the extra effort necessary to operate and maintain the detector worthwhile.

### 6.6.4 Other Detectors

A number of other detectors such as electron capture, photoionization, and pulsed ionization discharge have been used in PGC applications, but the use is minimal for the trace analysis of compounds which contain molecules specific to these detector types. The details of the operation of these detectors are beyond the scope of this article. Further information and discussion can be found in the list of references.\(^{(12)}\)

### 6.7 Carrier-gas Pressure/Flow Control

The control of the carrier-gas flow rate is of critical importance to PGC to obtain repeatability of peak areas and retention time for the components being measured. Either pressure regulators or flow controllers may be used for flow control, but for PGC pressure regulation is preferred. Pressure regulation can provide the necessary column flow rate when there are downstream stream leaks in the system. Ambient temperature changes are not as critical with pressure regulation. The most important reason for selecting pressure control is the use of valve and column switching to perform the separation. A pressure regulator has a much faster response to downstream upsets than is possible with a flow controller, which is dependent on its flow setpoint. The selection of a pressure regulator for a process chromatograph includes parameters such as operating pressure range, limitations of amount of flow it will pass, cost, ambient temperature, and barometric pressure changes. The most critical of the parameters for automatic, continuous GC operation are the effects of ambient temperature and barometric pressure.

For a pressure drop across a column of approximately 5 bar, the error in peak area will be 1.5 times the relative error in pressure drop. To limit the error to within 0.5% the pressure control must be within 0.03 bar. If the same regulator is referenced to ambient pressure, the error resulting from barometric pressure variation will be 1.4 times the variation. As can be seen, variations in ambient temperature and pressure can cause 0.2–0.5% errors in the results.\(^{(19)}\)

The recent introduction of electronic (microprocessor) pressure control corrects for many of the variations. In addition, electronic pressure control allows chromatographers to make use of pressure as a variable to improve separations. Pressure programming can be used to reduce cycle times and pressure-switching techniques can be employed to simplify GC multicolon, multivalve switching configurations. The proportional valves and transducers in the electronic pressure-control system are located in a temperature-controlled housing which isolates the temperature-sensitive components from the ambient environment. This feature eliminates or greatly reduces the ambient temperature effects normally present with pressure regulations. As a result, the repeatability and reliability of the pressure/flow control are greatly enhanced.

With the electronic pressure-control system, pressures are set directly through the microprocessor controller keypad or remotely from the analyzer data control system. The actual pressure readings can be viewed through the microprocessor controller front panel interface. The electronic pressure control package includes control electronics, a manifold block housing, multiple proportional control valves, and pressure sensors. Each pressure sensor is located downstream of the proportional valve (Figure 15). If a downstream pressure change is sensed by the pressure sensor, a signal is transmitted to the control electronics which correspondingly sends a signal to the proportional valve to raise or lower the pressure and corrects for the pressure change at the transducer. The feedback control scheme occurs at a very rapid rate, resulting in very repeatable and smooth pressure control.

This introduction of electronic pressure control provides increased reliability and precision from the PGC system. In addition, microprocessor control of flow settings allows fast and easy implementation of this otherwise tedious process. Pressure programming, which is possible with this type on pressure control, complements traditional temperature programming which will result in even faster analysis cycle times. The true benefits of this capability for PGC applications will continue to evolve as the need for faster and more complex applications arise.

![Figure 15 Schematic diagram of electronic pressure control.](image)
7 APPLICATION ENGINEERING

Unlike its laboratory counterpart, most process gas chromatographs are designed to perform one specific application. In a few situations, multiple streams will be measured with a single chromatograph, but the stream composition must be similar in nature for this to be possible (chemical components and concentration). The first step is to review the sample stream composition. This includes the temperatures, pressures, measured components, concentrations, and the nonmeasured stream matrix. Based on this review, the stream will be sampled as a liquid or a gas. Next, the column and valve configuration is determined to allow the measured components to be separated and measured in the minimum analysis cycle time. A detector and carrier-gas must be selected to provide the required sensitivity and repeatability.

The analysis cycle time is critical for control of the process from which the sample is taken, and is critical to the column valve configuration selected. There is often more than one configuration possible for a particular application and things to consider other than cycle time include hardware requirements (valves, columns, and detectors), cost, and simplicity. It is very important to the reliability of the measurement to keep the application as simple as possible. This will result in increased reliability and ease of maintenance.

Once these choices have been made the valves and detectors necessary for the application are installed in the analyzer. Next, the columns, flow rates, and temperatures necessary to provide separation of the components of interest are determined. It may be necessary to adjust these parameters to obtain the optimum repeatability of the method. Column selection requires experience and understanding of the basic parameters such as temperature, flow rate, length, diameter, liquid phase, and phase loading which affect separation. The columns and operating conditions are normally provided as a part of the total chromatographic solution from sampling to data reporting by the process gas chromatograph vendor. In the case of a reapplication it may be necessary to go through a great deal of experimentation, refer to references in the literature, or, probably the best approach, consult with someone who has experience with the particular application, in order to select the best columns for a specific analysis.

The most recent innovation in application engineering involves the utilization of more than one detector to perform a specific analysis. This approach allows components with a wide range of concentrations to be measured, provides faster cycle times, and eliminates or reduces interferences from other components. In the author’s opinion, this approach should not be utilized for the sole purpose of reducing the number of analyzers necessary for reliable process control. The combining of applications within a single analyzer often results in a complexity of hardware which renders the analyzer unreliable and difficult, if not impossible, to maintain.

When the analyzer has been configured, a sample representative of the stream to be measured is obtained and the analyzer is evaluated for sensitivity and repeatability. The analyzer is calibrated using a calibration mixture with a composition representative of the stream to be measured. With the advent of microprocessor controllers, this process is as simple as entering the concentration of each component in the mixture. The controller, in turn, calculates a response factor for each component. The configured analyzer ready is to be put on-line, automatically taking samples, separating the components, measuring the concentrations, and outputting the results needed for process control.

8 CALIBRATION REQUIREMENTS

The calibration methods employed for PGC utilize external standards, with a comparison with a known concentration of components in a prepared mixture, comparison with a laboratory analysis, grab sample, benchmark, and internal normalization.

The most commonly used technique is an external standard where a cylinder of calibration gas or liquid is periodically analyzed by the chromatograph. The concentration of each component is entered in the microprocessor controller and the response factors are automatically determined. The response factors are subsequently used to calculate the concentration of the components measured in the process stream. Peak areas are multiplied by the specific response factors for each component. A less expensive approach is to use grab samples which are taken from the process stream and analyzed by the plant laboratory. Often large quantities of a process sample are taken, analyzed, and used for “benchmark” calibrations. This is an inexpensive alternative to buying expensive, commercially blended calibration standards.

This technique is often used for simulated distillation samples which involve a large number of components which are difficult and expensive to blend. Internal normalization is potentially the most accurate method, but this requires the measurement of all components in the sample and a microprocessor controller. The limitation is the cycle time required to measure and separate all the components in the stream.

A further requirement of a calibration standard is that it be stable over a long period of time. Reactive components or components which absorb strongly on cylinder walls result in erroneous calibrations over time.
Three approaches to overcoming this problem of reactivity of standards involve permeation systems, calibrations with response factors, and surrogate samples. Permeation systems utilize permeation tubes which are liquefied samples contained in a permeable membrane. The permeation rate of these tubes is dependent on the vapor pressure of the liquid, temperature, and permeability of the membrane used. The permeated sample is diluted to the concentration required using inert gas and may be further diluted with air to attain parts per million and billion levels. The second technique involves calibration of a single nonreactive component and the use of response factors for a specific component with a specific detector type obtained from the literature. Although this technique introduces some error, in some cases it is the only option available. The results from the one component used for calibration are used to adjust the literature response factors. Finally, if the components are toxic or very reactive, it is often necessary to find a surrogate sample that has similar chromatographic characteristics to use for calibration. An example of such a sample may be halogen-containing compounds or chemical agents used in chemical warfare.

Regardless of the technique used, calibration is critical to the accuracy of the chromatographic application. The precision of the analyzer is dependent on repeatability, sensitivity, and linearity, but to be truly accurate the analyzer must be properly calibrated. This is a long-term requirement and the responsibility of the user. The frequency of calibration is another commonly asked question and is dependent on the application. The use of a microprocessor controller and automatic calibration with tolerances established for each response factor help to solve this problem. Using these features inherent to the modern GC system the response factors are automatically updated if they change by an operator selected percentage of the previous values.

9 SAMPLE HANDLING AND CONDITIONING SYSTEM

The sampling system employed is the major factor in determining the success or failure of most PGC applications. It should, therefore, be designed as an integral part of the total analyzer and not as an accessory. The sampling system should contain the components necessary to condition and maintain a constant flow of sample into the analyzer. This system may include pressure reducers, driers, filters, vaporizers, cooling units, flow controls, and sample stream-switching valves for multiple stream applications. There are three major aspects of the sampling system that must be considered.

1. Sample point location
   The sample point should be located so that the sample is representative of the process stream, but the location should also minimize the complexity and time delay of the sample system.

2. Sample conditioning
   In the simple case of a process stream with positive pressure, the sampling system may consist of no more than a filter and pressure reducer. A flow meter for setting up and checking the system is desirable. In many cases additional hardware will be required for heating or cooling and drying the sample, for the removal of mists and droplets from gases or of entrained vapor from liquid samples, and for scrubbing out corrosive or unwanted substances such as particulates. In addition, sample pressure may have to be changed using pumps or pressure reducers. Filters, driers, and heaters should be mounted in pairs with appropriate block isolation valves, so they can be serviced without interrupting the sample flow. It should be pointed out that the sampling system must deal with all process stream compositions and conditions, not only with a stream corresponding to ideal operation of the process. In the case of sample streams that require extensive cleanup, the sample conditioning system may resemble a miniature processing plant. An additional requirement of the sampling system is that it should not change the sample in an undesirable manner through reaction or polymerization at elevated temperatures, through either selective evaporation or condensation, or by adsorption.

3. Dynamic response of the sample system
   The performance of a sampling system must also be considered in terms of the response time to a step change in concentration at the stream input. Minimum lag time is critical for the high-speed analyses necessary for closed-loop control. To facilitate this, the number of components necessary for sample cleanup should be kept to a minimum and the sample flow rate maximized. \(^{(20)}\)

10 INSTALLATION REQUIREMENTS

The pneumatic and electrical requirements for installation for process gas chromatographs are similar to those required for other process analyzers. With certain detectors there are special support gases needed. There may also be sampling lines which must be heated or cooled to maintain temperatures which will allow a representative sample to the analyzer. The analyzer should be located to protect it from the elements, with a minimum being a three-sided shelter.
Although many of the modern process gas chromatographs can perform reliably under a variety of environmental conditions, it is best to install the gas chromatograph in a climate-controlled analyzer shelter. The actual level of control needed depends on the ambient temperature range and the concentration levels being measured. Each process chromatograph manufacturer provides a published temperature range for the analyzer within which the analyzer may be operated and still meet specifications. If the analyzer is measuring trace levels of components in a process it is operating at maximum sensitivity and wide ambient temperature variation will render the analyzer unreliable without adequate ambient temperature control. Most analyzer shelters provided incorporate both heating and cooling systems for precise temperature control. A process gas chromatograph is a complex integrated analytical system and maintenance must be performed in a variety of weather conditions. The necessary maintenance is much more likely to occur if the analyzer is housed in a climate-controlled analyzer shelter. These special installation requirements for a process gas chromatograph result in an installed cost of 3–4 times the cost of the analyzer, but without the necessary attention to installation the analyzer will not provide the accurate, reliable results needed for process control.

11 CONTROLLER/PROGRAMMER

The controller or programmer (the terms are often used interchangeably) is the electronics normally housed on top of the chromatographic analyzer oven section. The primary purpose of the controller/programmer is to act as a sequencing device and control all the functions of the analyzer. These functions include sample injection and column switching, stream switching, autozeroing, peak gating, integration of peak areas, calculation of concentrations, diagnostic functions, and transmission of data, all of which are done on a cyclic basis. Modern chromatographs use microprocessor- or personal computer (PC)-based electronics coupled with various types and sizes of memory located on plug-in circuit boards. For the typical chromatograph the current or voltage from the detector is transmitted to the detector electronics, where it is amplified and fed to the analog-to-digital conversion electronics. The digitized signal is transmitted to the microprocessor, where resident response factors are used to calculate the concentration of each component in engineering units. The concentration values are output to a printer or another computer system.

The serial data output is often provided as redundant outputs to reduce the possibility of failure of one of the data transmission lines. In the event of a power failure, on-board electrical erasable programmable read-only memory is used to save the latest version of the program used in the application. When power is restored the system automatically reloads the program for normal operation. Other forms of memory backup such as batteries and magnetic tapes have been used to reload the program.

Other features of the control electronics include hardware and software diagnostics and indicating lights on the front panel to signal a problem. Recently introduced capabilities include the settings of temperatures, readout of temperature setpoints, pressure settings, and read-out of pressure setpoints. The ability to set and control these two critical parameters through the microprocessor greatly enhances the reliability and precision of the analyzer. Basic calculations using the concentration values in combination with other analog signals are possible in the microprocessor-based controller/programmer. These calculations can be done in real time using an operator-entered program to calculate a desired process variable. An example is the heating value per unit volume of gas for a gas-processing plant. The gas flow rate would be an auxiliary analog input from a gas flow meter.

Finally, the validation of the data is performed in the microprocessor controller/programmer. Based on the results of the analysis such as total peak area, response factor changes, and retention time shifts, validation codes can be assigned to the data prior to transmission to a control computer to allow a decision process to be made on the usefulness of the data for process control.

The front panel of the programmer controller has an operator–machine interface which consists of a keypad and monitoring device such as a cathode-ray tube or liquid-crystal display. This allows the operator to enter and modify the program for a specific application. The monitor is also very useful for diagnostic purposes such as display of alarms and readout of variables such as temperature and pressure. Although a chromatogram is usually available on the monitor, it is a digital version and lacks resolution for troubleshooting purposes when there is a valve, column, or detector problem. Problems with these devices can be analyzed using the recorder output (located on the front panel) connected to a strip-chart recorder. Note: many plant environments would require the maintenance person to obtain a hot work permit prior to connection of such a recorder.

12 DATA SYSTEMS

The modern data system consists of microprocessor- or PC-based computers used to multiplex several process gas chromatographs into single or multiple distributed control system (DCS) computers. Earlier versions served
CHROMATOGRAPHY IN PROCESS ANALYSIS

13 OTHER CHROMATOGRAPHIC TECHNIQUES

There are other techniques which have been developed to separate and measure components of process streams. Each offers unique applications or sample types which make them complementary to PGC. A limitation of a process gas chromatograph is that the sample must be volatile, that is, we must be able to convert the sample into the gas phase. Any substance, organic or inorganic, which exhibits a vapor pressure of at least 60 torr (8 kPa) GC can be eluted from a gas chromatograph column.

There are many samples which cannot be vaporized because of the temperature levels required, and many that fragment or decompose when raised to a temperature sufficient to vaporize them. These include compounds of higher molecular weight, inorganics, complex molecules, and thermally labile compounds. For these sample types alternative chromatographic techniques may be used. Two of these techniques, LC and supercritical fluid chromatography, will be presented.

13.1 Liquid Chromatography

While only a small fraction of the known organic molecules can be separated using GC techniques (because of volatility limitations), virtually all the known organic molecules could be separated with LC techniques. However, the application and reliability of the technique have been limited because of the complexity of the hardware required. To understand these limitations better, we need to look at differences between GC and LC.

The principles behind the two separation techniques are basically the same, the major difference being that in LC the sample is dissolved in the liquid mobile phase, whereas in GC the sample is carried through the system with a gaseous mobile phase. In both, the separation occurs owing to the solubility or absorption of the sample on the stationary phase contained in the column.

An LC separation occurs by taking a sample with a sample valve (rated for high-pressures). The sample is injected into the mobile phase where it is dissolved and is moved through the column with a high-pressure pump. As the sample is carried through the column, it interacts with the stationary phase in the column and is separated into its various components. The greater the interaction by a specific component, the longer it takes to move through the column. As the components elute from the column, they are measured as they flow through the detector. The peak areas are used to calculate the concentrations of the components and the resulting data are used to control the process being monitored.

Several types of high-pressure pumps have been developed to drive the liquid mobile phase through the column system to the detector. These include syringe-type, pneumatic amplifiers, diaphragm pumps, and positive-displacement piston pumps, all capable of pressurizing to liquid mobile phase to several thousand pounds per square inch. The detectors most commonly used for process chromatography are ultraviolet and refractive index detectors.

The ultraviolet detector has a source of radiation, a method of selecting the specific wavelength, and a
detector for measuring the amount of energy transmitted through the sample stream. This detector type is capable of measurements in the parts per million and billion range. The wavelength selection is performed by either a monochromator or an interference filter.

The refractive index detector measures the change in refractive index that results from the sample dissolved in the mobile phase. It is less sensitive than the ultraviolet detector, but is more universal. The effects of temperature and mobile phase changes in composition limit the applications possible with this type of detector.

The complex design and reliability of the pumps and detectors have limited the process applications for LC. They are advantageous over gas chromatographs for applications involving samples with a very high boiling point or samples that decompose when vaporized. For these applications, the technology has been widely used in pharmaceutical and polymer industries.\(^{21}\)

The limited application by other industries has led to the discontinuation of all commercially available process LC analyzers. This leaves the potential users of process liquid chromatographs only one choice, to adapt a laboratory system for the particular process application. When considering such adaptation, one must keep in mind environmental and safety constraints, automatic, continuous operation, and the long-term maintenance requirements of such systems.

### 13.2 Supercritical Fluid Chromatography

The application range of process gas chromatographs is somewhat restricted by the limited volatility and thermal stability of many organic compounds. Mixtures of less volatile compounds can be analyzed by LC (described in the previous section) or high-temperature GC, but these techniques have not found a lot of acceptance as process analyzers.

Another form of chromatography, using supercritical fluids, gained wide popularity in the laboratory during the 1980s. Supercritical fluid chromatography combines several features of GC and LC, which make it an ideal technique for analyzing samples of low volatility and thermal stability. In addition, this technique has been shown to be easily adaptable to “on-line” process chromatography.\(^{22}\)

Supercritical fluid chromatography is a chromatographic technique that uses supercritical fluids as the mobile phase. When a gas is heated and compressed above its critical temperature and pressure it exhibits properties that are intermediate between those of gases and liquids. The most important property is that the density varies as a function of the temperature and pressure; as the pressure increases, the density increases, increasing the solvent strength. Consequently, by varying the pressure, the solvent strength can be adjusted, thus changing the partitioning of the sample between the stationary phase and the supercritical fluid mobile phase. Other properties related to the density include diffusion coefficients less than that of a gas, but greater than that of a liquid, and viscosities similar to those of gases, but much lower than those of liquids.

Taken together, these characteristics lead to a number of differences with respect to GC and LC. For example, because the diffusion coefficient is greater in a supercritical fluid than a liquid, one can achieve higher resolution and faster analysis times for the same conditions when using a supercritical fluid rather than a liquid mobile phase. Viscosity also plays a major role in the transport properties of the supercritical fluid through a column. Since the viscosity of these fluids is similar to that of a gas, the pressure drop across the column is low. This allows the use of capillary columns, which helps to expand the analytical capability of this technique.

There are several supercritical fluids available, but carbon dioxide is most commonly used because of its low critical temperature and pressure. Carbon dioxide has an intermediate polarity, making it the ideal solvent for a wide range of samples. It is nontoxic and has no response on an FID.

There are several key hardware components that make it uniquely different from other process chromatographs. The pump is a pneumatic amplifier, which provides the pressure to keep the system supercritical and generates a programmed pressure ramp to elute the components of interest in the sample matrix. The pump is controlled by a microprocessor and is capable of delivering pressures from 1000 to 7000 psig.

Packed or capillary columns may be used for a separation. For packed columns, 1 mm internal diameters are used and for capillary columns 0.1 mm internal diameters or smaller are common. Because of limited sample capacities, direct injection of sample is not recommended owing to overloading of the column. For GC applications this problem can be overcome by using a splitter. The use of splitters for supercritical fluids has been found to be very unreliable and non-reproducible.\(^{22}\)

To avoid sample splitters, the process supercritical fluid chromatograph uses a sample diluter, wherein a microliter-size sample is injected into a chamber filled with supercritical fluid. The sample is dissolved and mixed in the chamber and a fixed volume of the diluted sample can be injected on to the column, thus eliminating the need for a splitter.

The final critical component is the column detector interface. An FID requires the column effluent to be depressurized to ambient pressure prior to detection. This is normally accomplished by using a capillary restrictor.
The major application area for the supercritical fluid chromatograph is the petroleum industry. The mild conditions of this technique make it ideal for the analysis of high-boiling petroleum fractions. The samples are dissolved in the supercritical fluid and separated at temperatures of less than 100°C. This eliminates the fractionation which often results when these samples are vaporized.

13.3 Preparative-scale Chromatography

Often in the literature, preparative scale is referred to as process chromatography. This technique involves a large-scale chromatographic system that uses wide-bore columns of 10–20 cm internal diameter to isolate milliliter volumes of a component from the balance of the sample. This large liquid chromatograph is very similar in operation to a pilot plant used to simulate a process. Although the term “process” chromatograph is used to define this analyzer, it is not considered to be a part of the family of chromatographic techniques used to measure and monitor sample streams for process control.

14 COMMON APPLICATIONS

The uses of process gas chromatographs in industry are limited only by the imagination of the process control engineer. This analytical tool is suitable for any application where a sample can be introduced in the gas phase, the components of interest can be suitably separated on a chromatographic column, and reliably measured by a compatible detector.

Some of the more common uses include the following:

- Process control: use information to adjust the process with open- or closed-loop control.
- Process study: obtain information about the process to improve yield or throughput; correlate process variables with product quality.
- Process development: obtain information about the process characteristics as in pilot plants; correlate process variables with reaction products and yields.
- Material balance: use information to calculate material balance for the process unit.
- Product quality specification monitor: monitor impurities in incoming or outgoing product for conformance to specifications.
- Waste disposal monitoring: monitor liquid or gas effluent wastes for loss of valuable product or for presence of toxic compounds.
- Personnel safety–air monitoring: monitor ambient air for the presence of toxic compounds.

Of course, the most common of these uses is the use of information for open- or closed-loop control. In open-loop control, the operator uses the results to make adjustments to the process. In closed-loop control, the results are input to the central process control computer which, in turn, automatically makes adjustments to the process.

Before selecting a process gas chromatograph for online analysis in any industry, two important questions must be answered. First, will the analyzer provide information that will allow the plant to save money or provide increased safety of personnel or protect the environment? Savings can come from many sources such as increasing the throughput of a chemical product, reduce the losses of valuable raw materials, upgrade the value of a product, or conserve energy. If one cannot identify an economic benefit, the installation and maintenance of a process gas chromatograph may not be the right decision. Some chromatographs must be installed without direct economic justification for the protection of workers from toxic emissions and to protect the environment in the plant and the surrounding community.

Second, is there a better, less expensive technique to measure the components of a process stream? As technology evolves, alternative instruments such as mass spectrometers, spectrometric analyzers, and electrochemical analyzers are being introduced for process applications on a continuing basis. The benefits of chromatography include the ability to separate the components of interest from complex mixtures and to obtain quantitative and qualitative results at a reasonable cost. The gas chromatograph is also the analyzer of choice when multiple streams and multiple components must be measured in a wide concentration range. Many analytical techniques look promising when applied to binary mixtures, but they fail miserably when installed in real-world process applications.

Considering the more than 30,000 process gas chromatographic analyzers installed since the late-1950s which continue to operate in plants today, one finds very few references describing these applications. Much of this is due to the proprietary nature of the process applications, and another reason is that there are many classes of applications where there are only slight variations.

14.1 Petrochemical/Chemical

Petrochemicals include chemicals or chemical products derived from hydrocarbon raw materials, primarily crude oil and natural gas. They account for the majority of the production of chemical manufacturing industry. Catalysts, thermal cracking, fluid flow, heat transfer, mass transfer technology, equipment, and materials are used to convert hydrocarbon raw materials into primary petrochemicals.
These are used as feedstock for further processing into intermediates or petrochemical products.

The volume plastics business is a good example of petrochemicals produced by this industry. Plastics including several types of polyethylene (PE), polypropylene (PP), and polystyrene (PS) account for approximately 70% of all petrochemicals because of their widespread use in packaging, automotive, construction, electronics, and other markets. Ethylene and propylene plants utilize numerous process gas chromatographs (approximately 60) to control the manufacturing processes. A typical application that utilizes a process gas chromatograph is the ethylene cracking process.\(^{24}\)

### 14.1.1 Cracking

Low-molecular-weight feedstock (ethane, propane).

Measurement: furnace inlet, \(C_1, C_2, C_3, C_4\) compounds; furnace outlet, \(C_2, C_3,\) and \(C_3;\) and ratios of \(C_1 : C_2\) and \(C_1 : C_3.\)

Analysis time: 10 min.

Detector: TCD.

Purpose: furnace inlet. Determine the quality of feedstock to predict yield.

Furnace outlet: the correlating parameters used within industry are severity and selectivity. Severity measures the extent of the pyrolysis (also known as conversion) which can be determined by the methane (\(C_1\))/propylene (\(C_3\)) ratio. Selectivity is a measurement of time–temperature history. Coke deposition in the heater coils and effluent exchanges raise the pressure in the coil, favoring the production of methane and liquid products rather than light olefins. The methane (\(C_1\))/ethylene (\(C_2\)) ratio is used for correlating selectivity. A gas chromatograph can be used to measure the three compounds, the ratios calculated, and the entire yield structure predicted.\(^{25}\)

Benefit: feed-forward control of the furnace.

Typical furnace feed and furnace effluent composition: see Table 1.

The chromatographic separation of the ethylene furnace feed (ethane/propane) is shown in Figure 16. The column–valve configuration utilizes a backflush to measure valve to group pentane plus heavier hydrocarbons followed by the separation of methane, ethane, propane, isobutane and \(n\)-butane.

The chromatographic separation of ethylene furnace effluent is shown in Figure 17. The column–valve configuration utilizes two sample/backflush valves operated in series and four separation columns.

Other common chemical/petrochemical applications include alcohol production, distillation control, reactor product analysis, ammonia production, vinyl chloride production, aromatics production, chlorine purity, PP production, methyl chloride production, styrene production, methanol, and naphthalenes production.

### 14.2 Refining

Today society around the world is dependent on motor vehicles as a means of transportation of people and products. The automobile industry is the single largest user of petroleum, consuming approximately 70% of the total.
products. The demand for fuels to power these motor vehicles continues to grow as our populations and economies increase. Supplying these fuels has grown into one of the largest industries in the world, involving exploration for crude oil, refining, marketing, and distribution of the finished product.

The modern refinery is a complex network of pipes, vessels, and reactors, but if one breaks it down into individual units, it is really fairly simple. The initial step is to take crude oil and separate out the natural gasoline present. Next, the refinery takes the remaining crude and uses various reactions to make more gasoline. For example, the alkylation unit in a refinery is used to make octane from the reaction of two molecules of butane. Other reactors are used to break apart molecules too big to be used in gasoline by catalytic cracking or thermal decomposition in a coker. These reactors must be monitored and controlled, requiring analytical measurements which are easily provided using process gas chromatographs. A typical application utilizing a process gas chromatograph is the crude distillation process.

### 14.2.1 Crude Distillation

**Crude oil.**

**Measurement:** Various fractions including fuel gas \((C_1, C_2, C_3)\), wet gas \((C_2, C_3, C_4)\), light straight-run gasoline \((C_5, C_6)\), heavy straight-run gasoline \((C_7-C_{10})\), kerosene \((C_9-C_{15})\), diesel \((C_{13}-C_{18})\), gas oils \((C_{13}-C_{45})\), and residuum \((C_{40+})\).

**Method:** temperature-programmed PGC, simulated distillation.

**Analysis time:** 15–30 min.

**Detector:** FID.

**Purpose:** The primary purpose of the process gas chromatograph is to analyze the fractions of the crude distillation tower for boiling-point distribution using simulated distillation. Economic incentives exist to upgrade from one fraction to the next by operating as close as possible to the boiling point specifications. As an example, gasoline is more valuable than kerosene, which dictates separating the maximum amount of gasoline possible prior to distilling off the kerosene fraction. Recent environmental mandates for reformulated gasolines also limit the volume of higher boiling components because of their inefficient combustion, leading to increased pollution.

**Benefit:** improved yields.

**Typical measurement range:** \(C_4-C_{12}\) hydrocarbons.

The chromatographic separation of a gasoline sample using temperature programming is shown in Figure 18. A liquid sample injection valve is used to inject a microliter-size sample into a capillary, nonpolar column. The capillary column is programmed from an initial temperature of \(60^\circ\)C to a final temperature of \(270^\circ\)C at \(30^\circ\)C min\(^{-1}\). The type of separation is commonly referred to as simulated distillation, separating hydrocarbons in the range from butane to dodecane and higher. The results can be used to calculate the boiling-point distributions of various hydrocarbon fractions.

Other common applications for the refining industry include catalytic reformer unit, aromatics fractionation unit, fluidized bed catalytic cracker unit, HF alkylation unit, sulfuric acid alkylation unit, pentane isomerization unit, butane isomerization unit, hydrotreater, and gasoline blending.

### 14.3 Natural Gas Industry

The natural gas industry provides a valuable source of energy that is used in homes and industries throughout the world. This industry is composed of four major functions: gathering, processing, transmission, and distribution. First, the gas wells are drilled and the gas is extracted and collected for gas-processing. In the gas-processing plant, the heavier hydrocarbons are removed and methane-rich gas is placed in a pipeline for transport. The heavy fraction which was removed is separated by a natural gas liquids (NGL) plant to produce pure chemical compounds for use by the petrochemical industry.

The gas transmission companies buy the methane-rich natural gas and transport it through an extensive network of pipelines to the gas distribution companies. Finally, the gas distribution companies buy the gas and distribute it to the residential or commercial user.

As the natural gas moves through the various functions, ownership of the gas changes and it is important for the new owner to be able to analyze the purchased gas for heating value, specific gravity or density, and composition. A process gas chromatograph is ideally suited to provide these three measurements. The gas is normally purchased on the heating value per unit volume of flow and as the gas
moves through the various stages the heating value will change as a result of removal of components, dilution, and concentration. Two common contaminants are air and moisture, which have no heating value but change the volume of flow. There are some special requirements for a process gas chromatograph used in these applications, such as limited utilities, simplicity of design, speed of analysis, and reliable operation. A typical application in this industry is the measurement of the heating value, specific gravity, and composition of the natural gas stream.

14.3.1 Heating Value

Natural gas pipeline.

Measurement: N2, CO2, C1, C2, C3, i-C4, n-C4, i-C5, n-C5, C6+; other components such as heavier hydrocarbons, neopentane, and H2S are sometimes measured.

Method: PGC.

Analysis time: 2–10 min.

Detector: TCD.

Purpose: this measurement is required on custody transfer points where ownership of the gas changes hands. In the past natural gas was sold by volume with a guaranteed heating value. More recently, as the price of gas increased, the need to measure the heating value became more important. A typical pipeline transports large volumes of gas and a small change in heating value can significantly change the price paid for the gas. Using the concentration of each component measured multiplied by the “ideal” heating value for each component, the microprocessor integral with the gas chromatograph calculates the heating value of the sample. Because the natural gas is not an “ideal” gas, a correction must be made for compressibility; all of these corrections are provided by the microprocessor controller.

Benefit: precise measurement of heating value for custody transfer.

A typical natural gas stream composition is given in Table 2.

The chromatographic separation of a natural gas stream is shown in Figure 19. The column–valve configuration utilizes three valves and three columns. The first valve is used as a backflush to measure valve to group the pentane plus heavier hydrocarbons. The second and third valves function as dual column valves to provide enhanced separation of the lighter fractions. Note that the order of elution is not what one would normally expect because of the multiple valve switches.

Other common applications in the natural gas industry include absorption gas plant, expander gas plant, and NGL plant.

14.4 Environmental Monitoring

The application of process gas chromatographs to environmental monitoring or ambient air monitoring is a result of a desire to provide a safer working environment for employees of various industries and to reduce emission into the local environment. Many of the chemicals used in the plants are toxic, explosive, or damaging to the environment in the event of a leak or process upset. Area monitoring allows an early warning of such conditions so that remedial action can be taken prior to disaster. Stack or incinerator monitoring, often dictated by governments to ensure minimum emission of hazardous materials, is controlled to minimum standards.

The limits on emissions of hazardous compounds are established by groups such as the Environmental Protection Agency (EPA), Occupational Safety and Health Administration (OSHA), and local, state and federal governments. Such standards are often set for both air and water pollution. A monitoring program is normally established for hazardous compounds that may be present in the plant environment at regular intervals or on a continuous basis.

Because of the sensitivity of the detectors available for the process gas chromatograph, it is ideal for monitoring plant environments where the concentration levels are in the parts per billion range. In addition, because a chromatograph can be used to measure multiple streams, a single analyzer can monitor 20–30 sample points around the plant. The critical issue relative to the number of sample points is the analysis time of each point. For this

reason, the typical chromatograph used in this type of application only measures one component or, at most, two or three. The system is designed to trigger an alarm if the safe limit for the component being measured is exceeded. Another requirement often provided as a part of such systems is the long-term storage of data for later verification.

The reliability of the analyzer is very important since frequent maintenance would allow a plant to become unsafe without the knowledge of the workers. Analyzers used for environmental monitoring are often maintained by people within the plant who are not familiar with process gas chromatographs, such as the plant safety department. For this reason, the analyzers should be simple to operate and easy to maintain and repair.

14.4.1 Ambient Air Monitoring

Hazardous chemical compounds.

Measurement: trace levels of vinyl chloride, benzene, acrylonitrile, phosgene, hydrogen cyanide.

Method: PGC.

Analysis time: 1–2 min.

Detector: FID, other specific detectors.

Purpose: to protect workers and environment from hazardous compounds on a routine or continuous basis. The process gas chromatograph is usually designed to monitor one or two hazardous compounds in ambient air. If the concentration exceeds specified limits, the analyzer will trigger an alarm. A second alarm at higher specified limits may be used to trigger an evacuation of the area. The analyzer keeps average values for components measured over an 8h period, on a daily, weekly, and monthly basis, with reports logged at the end of these periods. In addition to providing these reports, the analyzer should be set-up to calibrate itself automatically on a regular basis. This will ensure that the analyzer is always working properly.

Benefit: protection of workers and the environment.

The chromatographic separation of hexane, benzene, toluene, and ethylbenzene in ambient air is shown in Figure 20.

Figure 20. A large sample loop (10mL) on a sample backflush to vent valve is used to inject the sample. Sample concentrations of a few parts per million can be measured with an FID.

Other common applications for environmental monitoring include industrial wastewater monitoring, incinerator stack gas monitoring, and fenceline air monitors.

14.5 Other Industrial Applications

Other industrial applications include the following:

- Biotechnology:
  - fermentation off-gas monitoring
- Pharmaceuticals:
  - solvent recovery
  - ethylene oxide sterilization
- Steel industry:
  - blast furnace off-gas analysis
- Food and beverages:
  - alcohol concentration
  - moisture concentration.

ACKNOWLEDGMENTS

The author thanks ABB Process Analytics Inc. for 30 years of employment in the exciting industry of process analyzers. During these many years he has traveled to many interesting places around the world, making presentations on the subject and sharing experiences with countless customers in the hydrocarbon processing industry.

The author also thanks his wife, Linda, for her assistance, encouragement, and patience during the few months in which this article was written. Without her support and understanding, this work would never have been completed.

Finally, the author thanks his secretary, Charlotte, who spent countless hours reading his terrible writing and typing and preparing this article for submission.

1 Introduction

Since the first paper on FIA appeared in 1975, the scope of the technique has grown tremendously, today ranging from routine analyses of wastewater samples in environmental labs to the measurement of the kinetics of drug uptake by single cells. One of the areas where FIA is most successfully applied is the monitoring of streams and samples in the process industries – on-line, at-line, and off-line. The roots of FIA as a process-monitoring technology date back to when the technique was in its infancy. The pioneers of process FIA came from the chemical and petrochemical industries, for example, Amoco, Dow, and Shell, in the late 1970s. The first review article on process FIA was published in 1981, and the first commercial process FIA monitor was introduced in 1983 by FIAtron, Inc. In 1990, a new generation of the technique, SIA, was introduced which offered some important improvements for process analyses.

The more than 9000 papers on FIA published since 1975 are a measure of the extensive activity in the field; however, these publications tell only part of the story. Since the late 1970s, a great deal of research and development on FIA has been conducted in industrial laboratories which, aside from scattered journal papers and presentations at conferences, has never been published. Most of this work has been targeted at the application of FIA to process monitoring, including off-line (i.e. plant laboratory), at-line, and on-line approaches. This article attempts to capture and describe the technology that has been developed by this work, by providing an overview of the application of FIA techniques to process monitoring. The task is made difficult because FIA-based process monitors that are successful are often not described in the open literature by the company for obvious proprietary reasons. Nevertheless, we primarily draw on our experiences and also survey the published research in English.

1 INTRODUCTION

The principles of flow injection analysis (FIA) and sequential injection analysis (SIA) are described as applied to industrial process monitoring. A brief history is followed by an overview of the fundamentals of FIA and SIA, with emphasis on injection methods and membrane-assisted sample processing approaches. A discussion of the design of process instruments focuses on simplicity, maintainability, and software development. Hardware issues affecting autosamplers, fittings, pumps, and valves are also discussed. Issues affecting method development, quality control, and method validation are examined using specific examples from the chlor-alkali and phosphate rock industries. The design and operation of on-line sample interfaces is then described in detail. Applications in the major industrial areas are used as examples – chemical, biotechnology, manufacturing, and environmental. Finally, strengths and weaknesses are delineated and prospects for the future are presented.
The FIA technique automatically combines several analytical functions into a method performed in a flowing stream, usually under computer control, in a short period of time (generally 15–60 s), with a minute amount of sample (generally using microliter volumes), with simple and robust hardware, with high precision (typically better than 0.5% relative standard deviation (RSD)), with relatively little waste (of the order of a milliliter per sample), and covering a broad concentration range from ppb (parts per billion) to wt% (weight percent). An FIA method can be generally divided into three stages, all performed in sequence in a flowing carrier stream pumped through narrow bore tubing.

The first stage is injection, in which the sample is measured and injected into the flowing carrier stream. This step is usually performed with a two-position injection valve.

The second stage is sample processing in which the analyte is transformed into a species that can be measured by the detector and have its concentration manipulated into a range that is compatible with the detector. There are a large number of different processing steps which can be performed on the sample zone as it flows through the FIA system. One common processing step is simple dilution – dilutions up to 1:10000 are possible with high precision. Conversely, enrichment up to a factor of several hundred may be possible in certain cases for trace analysis. For optical detector-based methods in general, some chemistry is performed on the analyte to convert it to a detectable form. One can also do on-line matrix modification and medium exchange. The former refers to moving an analyte from a complex matrix to a simple matrix before detection, whereas the latter refers to moving an analyte from a gaseous sample to a liquid carrier, or vice versa.

The third stage is detection where the analyte, or a derivative of it, generates a response that is used for quantitation. A large variety of flow-through detectors are used in FIA, primarily based on ultraviolet–visible optical or electrochemical transducers. It is beyond the scope of this review to describe in detail the various detectors that can be used with FIA. Several excellent monographs are available for this purpose.

The value of FIA as an analytical tool lies in its ability to combine these analytical functions in a variety of ways to create a broad range of methodologies, and to perform these methodologies rapidly and automatically with minute (microliter) amounts of sample. The last stage is, to a large extent, based on conventional technology. The first and second stages are the heart of FIA. The following paragraphs look in more detail at these functions, in particular how they are used in a process monitoring environment.
2.1.1 Sample Injection

The device most commonly used to measure and inject the sample into the FIA carrier stream is a two-position six-port commutating sample injection valve, the two positions being commonly termed load and inject. For years, HPLC (high-performance liquid chromatography) valves were used for this purpose, but this is now considered to be unduly expensive because HPLC valves are designed for high pressures, whereas FIA is a low-pressure technique. Low-pressure valves are widely used in FIA work. Important features that valves must have to be suitable for process FIA include high rotary positioning precision, fast switching, pressure limits to ~100 psi, a reliable fitting system, a rugged rotor and stator, and the ability to inject sample volumes from a fraction of a microliter to several thousand microliters.

Recently, a variation of conventional FIA, called carrierless or reverse FIA, was developed by Hach Corporation. In this approach, the sample serves as the carrier stream and the reagent (i.e. for a derivatization reaction) is injected into the sample stream. Obviously, this approach is well-suited to typical process monitoring applications where the quantity of sample is unlimited. The fact that a sample pump is not required is a critical advantage of this type of FIA instrument design.

2.1.2 Sample Processing

Dilution is a very common operation for process FIA monitors. There are several different ways to perform dilution, the most common being:

- dispersion
- electronic dilution
- zone sampling
- gradient chamber
- membrane sampling.

Dilution by dispersion is intrinsic to any FIA experiment. Controlled dispersion is one of the key processes in FIA, which disperses the sample into the carrier, both diluting it and mixing it with reagent. This technique is, without doubt, the simplest and most precise FIA technique for dilution. The smaller the sample, the greater the dilution; therefore, the key to large dilutions is the capability to precisely inject very small samples. The most precise tool for injecting extremely small volumes is a two-position sample injection valve with a fixed internal loop. Volumes as small as 0.2 μL can be injected, creating dilution factors of several hundred.

A disadvantage of the internal loop model of injection valve is that the volume is fixed, so that changing the volume requires changing the valve. A two-position sample injection valve with an external loop allows the volume to be varied conveniently. Generally, the volume is varied by manually changing the length or internal diameter of the external loop. However, valves with micro-electric actuators have the unique capability of timed injection, switching under software control. These valves permit partial-loop variable-volume injection with a fixed sample loop. Volumes from about 1 μL up to the total volume of the loop can be injected reliably.

Electronic dilution is a novel and simple technique for dilution which is also based on controlling dispersion. Electronic dilution simply refers to a technique for measuring the analytical signal along the detector response profile following the maximum where the signal is on-scale, as depicted in Figure 1. Generally, the signal is measured at the peak maximum, depicted as \( t_1 \). However, \( t_2 \) or \( t_3 \), which represent points in the sample zone where the sample is more highly dispersed or diluted, are equally valid points to collect the analytical signal. The timing of the signal measurement must be precisely controlled for this technique to work well. Electronic dilutions up to approximately 100-fold can be achieved. Although this approach is simple, it is probably the least precise of the dilution methods because of errors that are inherent in the measurement of a sloping signal, and errors because of slight shifts in the peak position.

Zone sampling is a relatively simple and powerful technique for dilution. It is similar to the heart-cut technique used in chromatography. It requires two sample injection valves. With the first valve, a relatively large sample is injected that then flows downstream to be dispersed by the reaction coil. As the dispersed sample zone fills the smaller sample loop of the second valve, an aliquot of the zone is injected into a second carrier stream. The second carrier can also pass through a reaction coil for...
further dispersion or dilution. Figure 2 depicts how this technique can remove a slice of the peak from the first injection for injection into the second carrier. Dilution by a factor of several hundred can be readily achieved. Precise timing of the two valves is important, requiring software or an electronic timer for optimal precision.

A gradient chamber is a simple device for dilution in FIA and SIA, as depicted in Figure 3. The gradient chamber is a small mixing vessel with a stirring bar and an inlet and outlet for the carrier stream. The volume of the chamber is generally 1 mL or less. The sample is injected into the carrier and disperses to a high degree as it mixes with the much greater volume of the gradient chamber. Dilutions by a factor of several hundred can be achieved with good precision.

The final type of dilution technique is membrane sampling. The use of a membrane sampling device (MSD) for dilution is relatively simple. A donor stream flows on one side of the membrane and an acceptor stream on the other side. The sample is injected into the donor stream and, as the sample segment passes over the membrane, a fraction of it is transported to the acceptor stream. The dilution factor depends on the sample volume injected, the thickness of the membrane, the surface area of the membrane, the channel dimensions in the MSD, and the flow rates of the two streams.

In addition to dilution, MSDs can be used for other sample processing operations, such as matrix modification, sampling of gas streams, solvent extraction, and analyte enrichment.\(^{18,19}\) The concept of using membrane permeation for sampling dissolved gases and gaseous samples has been applied in continuous flow systems primarily in clinical analysis since the early 1960s. Since then the technique has matured, with advances in membrane materials, sampler design, and flow systems. This approach has been demonstrated for gaseous samples and includes the determination of chlorine, ammonia, carbon disulfide, sulfur dioxide, and hydrogen cyanide.\(^ {20}\) Any gas that crosses a membrane and accumulates on the acceptor side may be suitable for membrane sampling.

Two membrane sampling designs that have been used widely differ in the membrane geometry: the parallel plate (or sandwich) design and the tubular design. In the sandwich design (Figure 4), a planar membrane is securely placed between two inert plates. Two carrier lines, i.e., a donor stream and an acceptor stream, pass through the MSD in separate conduits separated by the planar membrane. The donor stream can be either

gaseous or liquid, whereas the acceptor stream is liquid. The plates have engraved channels on their surfaces facing the membrane that define the volume for both the donor and acceptor streams. Separate tubing connections at the ends of each channel provide flow in and out for each stream. For gas–liquid separations, the gaseous analyte is introduced by the donor carrier stream into the planar membrane device where it diffuses through the membrane and dissolves into the liquid carrier stream. Only gases that can permeate the membrane and dissolve in the acceptor stream or react chemically with a reagent in the acceptor stream will be transported across the membrane. Hence, the selectivity advantage is dependent primarily on the membrane material. The acceptor stream is pumped through the planar membrane device and then out toward the detector.

The tubular or tube-in-a-shell membrane sampling design is also used widely (Figure 5). A thin-walled gas-permeable membrane with a tubular geometry is inserted into a larger cylindrical shell made of Teflon®, glass, or some other chemically inert material. The sample passes through the outer shell while the acceptor stream is stopped or flows slowly within the tubing. The tubular design is favored over the sandwich design because it is more resistant to leakage and the tubing length or geometry (linear, coiled, or knitted) can be conveniently varied to alter the contact zone surface area between the donor and acceptor streams. However, the wider availability of planar sheets rather than tubes of membrane material generally favors the parallel plate design for flexibility of use.

Either membrane sampling design can be used in a preconcentration mode by stopping the flow of the acceptor stream during sample collection. The stream to be sampled is kept at a constant flow rate so that the analyte is continuously transported into the acceptor stream. In this mode, equilibrium conditions favor diffusion across the membrane with time. If the analyte reacts with the acceptor stream to form a new compound, a concentration gradient will be maintained that will increase the rate of transport of the analyte across the membrane. That is, analyte that permeates the membrane will be swept off of the inner wall of the membrane into the acceptor stream solution upon reaction. The choice of the acceptor stream depends on the target analyte.

A number of different types of membranes have been studied and reported in the literature as MSDs for FIA. Most of them fall into three categories: nonporous (e.g. silicone or natural rubber), microporous (e.g. Teflon®, Goretex®, Zitex®, poly(vinylidene difluoride), poly(vinyl chloride), polypropylene, cellulose esters), and ion exchange (e.g. Nafton®) semipermeable membranes. All are available commercially.

The main difference that is of relevance to FIA among these types of membrane is the mode of mass transport across the membrane wall. With microporous membranes, mass transport occurs by diffusion of the analyte through the pores. Generally, these membranes are used with volatile analytes, such as dissolved CO₂, NH₃, H₂S, and HCN. In the case of nonporous membranes, the analyte actually dissolves in the membrane and diffuses through the wall structure to the acceptor stream side. Only neutral molecules have any appreciable solubility in silicone rubber, the most commonly used nonporous membrane, so this membrane does not work with ionic species. For this type of membrane to effectively transfer analyte from the walls of the membrane to the acceptor stream, the acceptor must have a much greater solubility in the acceptor stream than in the membrane, or become converted to a species with this property. Generally, this is achieved using a chemical reaction with a reagent in the acceptor stream that converts the analyte to a soluble ionic species. For example, for transport of NH₃, an acidic acceptor stream will convert the ammonia to NH₄⁺. The third type of membrane listed is ionic, where the transport of ions across the membrane wall occurs. The most common membrane of this type is Nafton®, which is a perfluorinated hydrocarbon polymer with pendant sulfonic acid groups. It readily transports small, monovalent cations, such as H⁺ and NH₄⁺.

The selection of a suitable membrane for the flow system depends on several factors. Optimally, the membrane will have good mechanical and chemical stability, will allow the complete transport of the analyte into the acceptor stream while simultaneously rejecting interferences, and will have an efficient transport rate over short sampling times. For gas-phase sampling, the analyte’s volatility, membrane permeation rate, and solubility in the acceptor stream affect the choice of membrane. Membrane porosity, pore size, and thickness will generally determine the collection and separation efficiency. The rate of mass transport across membrane walls is critically dependent upon the wall thickness. Namely, the lag time in analyte transport is proportional to the square of the wall thickness. Thus, thin-walled membranes with

Wall thicknesses in the range 10–200 µm are preferred for FIA work. Table 1 lists a representative number of membranes that have been used in gas-permeable MSDs.

2.2 Sequential Injection Analysis

SIA, which is a novel variation of FIA, has the primary advantages of simpler and more compact hardware, greater method flexibility, and less waste generation. The SIA technique offers an automated approach to sample handling that enables manual wet chemistry procedures to be executed in a rapid, precise, and efficient manner. Small solution zones are manipulated under controlled dispersion conditions in narrow-bore tubing. It is readily seen that this definition is quite similar to that given above for FIA. In fact, sharing many characteristics with FIA, many would argue that it is simply an extension of FIA.

More than 100 journal articles have been published on SIA since the first paper appeared in 1990. Although it is fundamentally dependent on the controlled dispersion of zones in a flowing stream, the practice of SIA differs from that of FIA.

A simple comparison is useful. Consider a single-line FIA experiment where one injects a sample into a carrier stream containing a reagent, as shown in Figure 6. A sample is pumped into the sample loop of a two-position injection valve and the carrier is flowing constantly through the detector. The length of the sample loop determines the volume of sample injected. When the sample loop is loaded, the valve is switched and the sample is introduced into a flowing carrier stream. The carrier transports the sample through the reactor (usually a coil) to the detector. The sample reacts with the reagent en route to form a detectable species. The detectable species gives rise to a peak when it passes through the flow cell of the detector. A calibration curve is then used with the peak height, area, or width to determine the concentration of the analyte in the sample.

However, SIA does not require an injection valve. Rather, a multiposition valve (MPV) replaces the injection valve, as depicted in Figure 7. Usually, the peristaltic pump is replaced with a syringe pump and a coil, called the holding coil, is added between the pump and selection valve. To achieve the same measurement as described above for FIA, the syringe is first filled with a carrier solution that contains the reagent. The selection valve is then advanced to a port that is connected to the sample line. A small volume of sample is precisely drawn into the holding coil. The volume of sample is determined by the computerized flow program. The selection valve is then advanced to a port that is connected to the detector, the direction of flow is reversed, and the carrier transports the sample through the reactor to the flow cell of the detector. Again, a detectable species is formed and is registered as a peak by the detector. The concentration of the analyte in the sample is determined in a similar manner as for FIA. The flow reversal has a dramatic influence on the mixing of stacked sample and reagent zones.

More often than not, instead of including the reagent in the carrier, an SIA experiment is expanded so that
the reagent is loaded as a separate zone. In this case the syringe is first filled with a simple carrier or buffer. After the sample zone has been drawn into the holding coil, the selection valve is advanced to a port connected to a reagent reservoir and a small reagent zone is drawn into the holding coil. In this way it is possible to construct a stack of well-defined zones which can be mixed together to give rise to a detectable species. Unlike FIA, which requires replumbing when a more complex chemical addition scheme is required, a change to the flow program is the only alteration for SIA. The manifold remains unchanged. The additional advantages of lowering reagent consumption and minimizing the production of potentially hazardous wastes are both important advantages of SIA.

The other ports of the selection valve can be used for calibration standards, additional reagents, and as locations where more sophisticated operations such as dilution, trace enrichment, and incubation of reactants can take place. For example, titrations can be performed by SIA whereby the reactor and detector in Figure 7 are replaced with a stirred titration cell. Appropriate sensors, electrochemical or optical, are placed in the titration cell which acts as the flow cell and titration chamber.

Researchers have applied SIA to the determination of analytes as diverse as trace radionuclides and biopolymers. Although SIA makes use of a simpler flow manifold (this is particularly so for multicomponent chemistries), the development of an SIA method is not as straightforward as in FIA. Careful attention must be given to the design of the measurement sequence to ensure that adequate zone penetration has taken place. Accurate measurement of sample and reagent zones necessitates microprocessor control. Of course, once the method has been developed, the microprocessor ensures slavish repetition of the optimized sequence. To summarize, several advantages can be identified of SIA over conventional FIA in the process environment:

- The selection valve replaces the injection valve and provides a means for selecting different sample streams and calibrants. This enables automated calibration and quality control.
- Components used in an SIA manifold are amenable to laboratory, field, and plant operation.

3 INSTRUMENTATION

3.1 Design Considerations

Because suppliers have often tried to place laboratory equipment directly in an industrial setting, many so-called ‘process’ monitors have come to pass. However, to be successful, a process monitor must be designed from the ground up. One only needs to examine the major differences that exist between a modern process gas chromatograph and a laboratory gas chromatograph to see a sterling example of this principle. As a case in point, there are custom-designed FIA multi-end-point titrimetric systems at a major petrochemical company, for example, that are still on-line even after 10 years or more of continuous monitoring. In contrast, laboratory systems for this analytical function were tested side-by-side to the custom systems and were inoperable after a 6-month period.

Contrary to popular belief, it is not only as a result of a lack of ruggedness that laboratory instruments are unsuitable for this application. The failure of laboratory systems in the plant can be attributed to the fact that too often the laboratory maintenance philosophy is applied to the plant environment. It is acceptable in the lab (though not desirable) to have a meticulous technician with tissue in hand to pamper the laboratory system, watching it closely for a new source of bubbles, tweaking a malfunctioning component, etc. In the plant, the monitor must be designed and constructed so that the scheduled maintenance for it can be completed in less than 30 min each week. No plant operator will be prepared to hover over the monitor to coax results from it. Where components are chosen and a process monitor is designed with these maintenance requirements in mind, and a disciplined and thorough scheduled maintenance program is established, the success of the monitor increases dramatically.

Another important design consideration is the sustainability of continuous improvements to the design. The literature is full of prototype process monitors which, although ingenious, did not outlast the time it took to generate data for a project report or paper. Industrial process monitoring is not the short-term project beloved of graduate school researchers. Therefore, the industrial process to be monitored should not outlive the process monitor’s
between 2 and 20 common; generally, the sample loop volume is small, and to minimize matrix effects. Fixed-volume sample loops mounted on or in six-port commutating valves are especially appropriate to process monitoring because the application is bound to be long-lived enough for continuous improvement of the process monitor to occur. This design philosophy can be summarized as follows:

1. Simplicity is imperative – the simpler the system, the easier it is to operate and maintain.
2. Design a system that will support a bullet-proof scheduled maintenance plan. Support the process monitoring system for the long haul.
3. Take note of the environment – most plant environments are hostile compared to laboratories. Allow the environment to suggest design constraints. A delicate and temperamental detector is probably not going to survive the rigors of the plant.
4. Carefully design the sampling system. More monitors fail because of an inadequate sampling system than for any other reason.

3.2 Manifold Hardware

Access to a process test bed for initial demonstration and continuous design improvement is important. Samples in process monitoring are often assays of major constituents, in complex matrices, and the challenge is to dilute the sample sufficiently to avoid saturation of the detector and to minimize matrix effects. Fixed-volume sample loops mounted on or in six-port commutating valves are common; generally, the sample loop volume is small, between 2 and 20 µL, to afford greater dispersion of the injected sample. The necessarily small orifice of the loop, however, may present a potential clogging point as the undiluted sample must pass through it during the loading step. This concern may be addressed by use of an efficient sampling system. If this becomes a problem, reducing the flow rate of the filling stream often helps avoid clogging. The precision in the response is typically <0.1% RSD with these types of valves.

The use of certain flangeless fittings can also be a source of blockages in valves. These types of fittings often rely on a ferrule that pinches down on the tubing. This reduces the tube diameter at that point and in the worst case can totally shut off flow. One solution to this problem is to insert a pin into the tube when the fitting is attached. This will keep the tubing from crimping closed and the Teflon® will rather cold-flow around the ferrule. Alternatively, commercially available high- or low-pressure compression fitting systems that use PEEK (polyether ether ketone) ferrules, nuts, bodies, and tubing are rugged, inexpensive, and easy to use. The rigid walls of the PEEK tubing prevent the kinking or pinching that occurs easily in thin-walled Teflon® tubing.

In general, the use of peristaltic pumps in process monitors is a major weakness. Again it comes down to the degree of scheduled maintenance expected. If examination of the peristaltic pump tubing (Tygon®) for wear is required too frequently, the plant operator will quickly lose enthusiasm for the utility of the monitor in controlling the process.

For single-channel monitors, a three-way valve can also be used for variable-volume timed injections. These valves are often less precise because multichannel peristaltic pumps limit the flow precision and thus the volume precision of a time-injected sample. Syringe or displacement pumps will increase the flow precision, but also increase the cost of each channel of flowing reagent or sample.

For a batch (off-line) FIA instrument, an autosampler is generally desirable so that the batches of process samples can be collected and analyzed at one time. The autosampler can contain nonsample vials containing calibration standards, reference samples, check standards, a wash bath for idle periods, and other needed overheads for batch analysis. The autosampler can be one of three types, random access (or XYZ), random access circular design, or sequential. An autosampler will execute a work list of samples usually stored in and controlled by a microprocessor. The autosampler is particularly suited to unattended operation of the monitor – the samples can be collected during the first shift, then the batch analysis can be started at the end of the shift with results available the next day.

For smaller batches or single samples, a manual sampler may be sufficient. These amount to an on-demand sampler, usually consisting of a sample tube or probe that can be placed into the vessel containing the sample or standard. The user then cues the instrument that the probe is in the correct sample. A manual or on-demand sampler may or may not automatically return the sample probe to a wash bath or container. An interesting hybrid batch/stream sampler can be arranged by placing one or more flow-through tubular baths, such as an autosampler wash bath, into the sample tube rack. A process stream can then be flowed through the bath. The autosampler
can thus sample the stream in the bath at any desired frequency.\(^{(26)}\)

A well-stocked inventory of spare manifold devices will typically be included as one of the provisions of a good hardware maintenance plan for a process FIA/SIA system. Modular design of the monitor will facilitate rapid replacement in the event of a break down.

### 3.3 Flow Injection Analysis Software

The rapid development of computer hardware presents an ever-changing spectrum of choices for the control of process monitors. The power of inexpensive computer hardware invites the development of sophisticated software packages, but increased sophistication does not necessarily result in a useful system. On the contrary, device control and data acquisition software for FIA systems should focus on enhancing the capability of the monitor to simply operate without error while unattended. Because hardware changes so rapidly, software must be scaled so that, as new platforms become available, rewriting the software is not necessary.

The FIA/SIA software to be used in a process environment will allow for method and schedule creation, editing, and execution as well as data analysis and quality control. Specifically, it will allow:

- precise timing of devices;
- data acquisition with the ability to filter data;
- automated calibration and quality control;
- results reporting via serial 4–20 mA analog outputs, with controller area network (CAN), FieldBus, or other industrial plant communications standards;
- display of trend data and calibration history;
- annunciation of alarms and warnings.

Because FIA and SIA techniques cover a wide range of unit operations and draw from a large pool of devices and detectors, it is imperative that good software allows a high degree of user configuration. This configuration should extend beyond the accommodation of different devices and detectors to also allow the user to determine the sequence that will be followed, i.e. when calibrations will be initiated, how frequently lines will be flushed, how samples will be presented to the monitor, and when measurements will be carried out.

Current software packages are frequently required to communicate their results to the plant’s distributed control system (DCS) where the information is used to control the process either in a closed-loop fashion or as an input that the operator will base certain decisions on. With the expanding use of intranets, it can be expected that these data will also be made available on the company intranet, so that other company personnel – management, accounting, shipping, etc. – can also have access to critical plant data. Hardware is already available to do this using embedded processors and appropriate network connections. The authors are not aware of any commercially available software that provides this as an option. To really exploit this technology though, software should go further and allow remote diagnosis of the process monitor via the company’s intranet. The ability to query the status of critical instrument devices, sample streams, and reagent reservoirs will reduce existing scheduled maintenance burdens.

### 3.4 Method Development

It is important for process monitor developers to understand the chemistry of the industrial process sufficiently to design appropriate analytical methods for the process monitor. This is especially important when replacing older techniques whose analytical chemistry may not be fully understood by plant personnel who are perhaps a generation removed from their invention and installation. For example, in the chlor–alkali industry\(^{(27)}\) which produces chlorine and sodium hydroxide by electrolysis of brines, it is important to know the concentrations of sodium chloride, hydroxide, chlorate, and hypochlorite in the electrolysis cells in order to maintain optimal current efficiencies, as electrical power is a major cost to this industry. An FIA process monitor would ideally measure all four cell-liquor analytes simultaneously without dilution. As each of the analytes is a major constituent, the FIA methods for each must be rugged enough to minimize the large changes in matrix concentrations and density across about two orders of magnitude in each analyte.

This particular industry breaks down into two separate applications and the analytical methods must be flexible enough to address both. The older plants have a mercury cell that uses liquid mercury as the cathode; the newer plants have replaced their mercury cells with cells using Nafion\(^{®}\) membranes to separate the anodic and cathodic processes. The two processes all have various concentration ranges which need to be anticipated; all ranges require precision of less than 1% RSD. During the design phase of the process monitor, the methods of determination are central. The methods must be developed in close consultation with the plant engineers and quality control chemists. Formerly monitored by titrations, batch colorimetric techniques, and segmented-flow analysis,\(^{(28)}\) FIA is replacing these techniques in many chlor–alkali plants.

The applications chemist who designs the method typically works closely with the process monitoring laboratory personnel to obtain representative samples, understands the matrix and concentration range of the analytes in the process, understands the method documentation and
validation used for process monitoring (on-line or laboratory), collects samples for method development, and negotiates and rationalizes any biases discovered between the current and proposed methods. Often the most familiar method to the process engineers and laboratory may not be accurate, but has a legacy of data standing behind it. The applications chemist must respect the use and consequences of the data obtained by the method. In this case, negotiation and diplomacy may count for more than proof of accuracy.

3.4.1 Calibration

Both laboratory (off-line) process monitors and modern on-line or at-line monitors can be calibrated frequently and the calibration standards set can be chosen appropriate to the application. Commonly, the monitor is calibrated once at the beginning of the batch or day, and the calibration is then regularly checked for drift by measuring one or two check standards during the batch, depending on the number of samples in the batch.

Designing calibration standards for a multiparameter process monitoring can be challenging. The expected concentration range in the process must be encompassed at once by a set of standards. For example, the chlor-alkali process requires calibration standards which contain four analytes ranging from 5 ppm to 250 g NaCl per liter, 0.5–2000 ppm sodium chlorate, and 1–150 mg sodium hypochlorite, all in 10–34% (w/w) NaOH. A certain degree of creativity is involved in designing a minimum set of calibration standards to span these ranges. Almost always, the FIA-based method is replacing the earlier method; however, the process client will often want to preserve the calibration standards from the earlier method. In this case, it is important for the method developer to understand fully the composition of these standards, which sometimes may be more venerable than accurate. If the method is to be transferable to other plants and sites within the industry, the calibration standards must be fully characterized.

3.4.2 Quality Control and Method Validation

It is common for an industry to develop their own internal reference samples and standards which must be respected as the final arbiters of accuracy and precision. For example, in the phosphate rock industry, the Chemists of the Florida Phosphate Industry\(^{29}\) have established a monthly phosphate rock check sample program. The samples are of two types, an analyzed rock sample and a series of pure polyphosphorus compounds. It is important for any newly developed FIA method intended for process monitoring to be included in such programs. In other words, the industry itself must be encouraged to validate the method with familiar reference samples. If the laboratory with the new method does well or is not rejected as an outlier among the various laboratories, then this method can be considered a process monitoring success. If the laboratory is rejected, for whatever reason, the developer must carefully determine the source of bias using the industry’s own check samples. The wise developer will obtain these samples and use them to check the new method before proceeding with validation.

Similarly, in the food, beverage, and fertilizer industry, any new FIA methods must perform similarly to the standardized methods they are replacing. For example, the Association of Official Analytical Chemists publishes a compilation of standard methods for the fertilizer industry, each of which has been subjected to one or more collaborative studies.\(^{30}\) In obtaining acceptance for a new, FIA-based method of analysis, it is important to identify plants and laboratories who historically have led the way in methods innovation as there is considerable inertia in changing from older, approved methods to anything new – even if it offers obvious advantages. Such clients are invaluable in gaining acceptance for a new method and will often fund or organize the necessary collaborative studies. Again, the use of the data and decisions that result from the data need to be respected; these are more important than the methodology itself to process engineers.

3.5 Sampling Systems

This category is divided into samples collected either at-line or on-line.

3.5.1 Grab Sampling

There are many examples of process monitoring in which grab samples are taken from the process and determined at-line, i.e. they are sent to a central laboratory for batch analysis by an off-line laboratory instrument. This is particularly the case in wastewater monitoring situations. Sampling problems can be the most daunting challenge for FIA process monitoring. For example, in the most benign application environment, the biotechnology industry, a continuous withdrawal of process solution would seem most desirable, and this is commonly done for headspace analysis. However, the bioprocess solution has a high suspended solids concentration and requires filtering in order to exclude the organisms and other solids from the withdrawn sample. Another potential obstacle is that withdrawing bioprocess solution continuously may open a path of infection to the bioprocess.

Such sampling considerations apply to the whole range of industries currently benefiting from FIA-based laboratory instruments: for the phosphate rock industry
and chlor–alkali industries discussed above, both have almost insurmountable on-line sampling problems – the sample is a solid or a superheated viscous liquid, in inaccessible sealed cells or large-scale inaccessible reactors, or are sampled seldom enough to preclude a permanent small-scale bypass or sampling stream. Thus, intermittent batch withdrawal of a sample is still the most common and flexible process monitoring sampling method. The batch sample, collected from anything from a shake flask, a 1000-L bioreactor, a tank car, an active electrolytic cell, the packaged product, condensed high-pressure steam, ores, sands, or concentrated brines from wells, can then be centrifuged, filtered, cooled, homogenized, labeled, ashed, crushed, preserved, and batched. The gamut of matrices, sources, temperatures, and pressures further complicates the sample collection process.

Generally, processes are monitored on a schedule determined by the plant engineers. The sampling frequency varies, from once every few minutes, to perhaps only once or twice a day. Grab samples are obtained through sampling ports by dipping containers, taps, etc., and the samples are bottled, labeled, and sent to the laboratory. This type of monitoring may be designed to validate or to show, after the fact, that a process was under control during the manufacture of the product, or designed to show an imminent need for process maintenance.

This may seem counter to the desire to obtain time-dependent data on the process. However, it is generally inefficient to run each sample individually to the laboratory to obtain a single data point – the entire calibration and quality control overhead must then rest on each single sample. Instead, usually a day or half-day’s worth of samples are run at one time, preceded by an instrument calibration, and interspersed with quality control samples. The size and frequency of batches depends on the predictability of the process. For processes under development or improvement, as in a bioprocess, smaller, more frequent batches may be necessary to be able to take corrective action. However, even these processes need a period over which a reliable trend can be established. For processes that have been implemented for some time in large-scale production, the trends have become so predictable that only a post-mortem type of monitoring is necessary. For example, in the chlor–alkali industry, over a period of time, an upward trend in sodium hypochlorite and chlorate concentrations will occur prior to Nafton® membrane replacement. However, this occurs only every 2–3 years. This maintenance schedule is predictable enough that these data serve only to confirm the predictable. Thus, a process that is useful at large scale does not necessarily need to be micromanaged.

3.5.2 On-line Sampling

On-line sampling is certainly more challenging, but the real-time nature of the analytical information provided makes it desirable, especially for pilot-scale process support. Collecting a representative sample from a process stream involves many paradoxes and trade-offs. It is rare that one has available a sample sufficiently pristine that it can be fed directly to the inlet of the selection valve (as in SIA) or loop of the injection valve (as in FIA). To derive meaningful information about the process, one must change the sample without changing the desired measurement variable, or change it in such a fashion that the degree of difference from true process conditions is known. The FIA method is somewhat more vulnerable to sample system influences than some methodologies, as these techniques use relatively small diameter tubing in their internal plumbing. The major advantages of FIA (mechanical simplicity and reliability) far outweigh the potential liability of sampling manipulation.

The chain of events typically involved in obtaining a sample are:

1. collection of the sample from the process, usually a pipe or tank;
2. transport of the collected sample to the location of the monitor;
3. conditioning of the sample for presentation to the FIA instrument;
4. introduction of the sample to the FIA manifold.

Of course, virtually every chemical process that might be subjected to chemical analysis is different from all others. It cannot be overemphasized that, to be successful, one must critically and completely understand the specific sampling situation. Despite the absolute criticality of the sampling system for successful instrument performance, unfortunately the design and engineering of sampling systems are often ignored or done as an afterthought when the performance of the installed instrument does not meet the desired performance goals.

3.5.3 Sample Collection

The first step in the sequence of operations required to obtain a meaningful on-line measurement involves determining how to gain access to the process stream. For practical reasons it is desirable to design the sample handling system to use a minimum number of additional devices. FIA has a significant advantage over many other modes of on-line analysis in that the quantity of sample required for a single determination is quite small – typically less than 100 µL. Thus, the overall amount of material that must be collected and processed can be significantly reduced compared to existing process
sampling methodologies. Four of the most common approaches to process sample collection for FIA are described in the following paragraphs.

Probably the most desirable sample collection approach is to simply tap across an existing process pump. This approach takes advantage of the fact that the capital expenditure (and maintenance responsibility) for the pump has already been made. In such an arrangement, a sample port is added to the exit piping and then routed to the desired monitor location. An output line is routed back to an inlet port on the upstream side of the pump (Figure 8). Samples obtained in this manner are well-mixed by virtue of their passage through the pump. The main disadvantage of this approach is that large (acute) process changes are recirculated through the fast loop and can lead to an increased analysis lag time. If such lag times are a problem, the recycled sample must be reintroduced into the process downstream of the take-off point at a low-pressure point in the process.

If a convenient process pump is unavailable, but the process is under sufficient pressure, a second sample collection approach is to introduce an in-line connection at a high-pressure point. Existing process pressure thereby provides the energy to force the process sample to the desired monitor location and back to a lower-pressure process point. It is tempting to make use of existing process connection points (blind flanges) to provide the connection points. However, extreme care must be taken in such cases to avoid various types of sampling problems. Blinded sidearms on piping runs typically are mounted at right angles to existing piping. If the piping run to which connection is desired runs horizontally, such right-angle mounting may place the sidearm on top of the pipe, on the side of the pipe, or on the bottom of the pipe (Figure 8). Each of the first two designs may present sampling problems. If connection is to the top of the pipe, gas bubbles will be preferentially routed into the sample line.

If connection is to the bottom of the pipe, suspended solids will be routed preferentially into the sample line. The preferred connection is to a sidearm mounted on the side of the pipe. Even then, it is probable that the volume of the sidearm will introduce significant time lags because it represents a large, stagnant volume of process fluid which must be diluted by the sample flow. The sidearm piping orientations are viable sampling points for the third design – the so-called ‘stinger’ (Figure 9). Note in the figure the shape of the end of the stinger and its orientation with respect to the process stream flow. This arrangement allows some additional discrimination against bubbles and/or particles flowing down the pipe. The stingers illustrated are all for the take-off point of the sample flow; the return point is not shown, being located farther down the process or at some other low-pressure point.

A fourth approach is to use a dedicated pump to provide flow through the fast loop to the monitor. However, this is usually not a popular option because it represents both additional capital and maintenance costs. Also, when such a pump inevitably fails, one typically finds in a plant that its replacement will always be a low-priority item compared to other maintenance emergencies. The net effect is increased monitor downtime and decreased monitor reliability. However, a dedicated pump does provide several advantages because it can be much smaller and less expensive than other options, and it does not require multiple taps into the process for extraction and return points (Figure 10).

The arrangement shown in Figure 11 shows the use of a flat-plate style of cross-washed inertial filter. Systems of this design are usually equipped with piping and a dedicated pump that are sufficiently large to allow the largest solids in the process to completely traverse the fast-loop piping. The fast-loop piping is typically 0.75 in or 1.0 in pipe. With the addition of automated valving and a different stinger style, the stinger system can become a fairly sophisticated means of prescreening the sample to reduce larger particles from entering and thereby permitting the use of a smaller cross-washed filter and
stingers. This design leads to significantly smaller piping in the fast-loop plumbing. Furthermore, the arrangement depicted also provides automatic backwashing of the stingers with the pumped flow. Each stinger alternately serves as a sample take-off and/or return point that depends on the position of the three-way valves. However, flow through the rest of the fast-loop tubing remains monodirectional to and through the smaller, tube-in-tube cross-washed inertial filter.

3.5.4 Sample Transport
Collection of the sample from the process location is only the first step in the chain of events that must occur before quantitative information can be derived from the on-line FIA monitor. Once withdrawn from the process, the sample must be physically transported to the relatively distant instrument. The rate of sample collection must be designed such that transport lag times remain within acceptable limits; that is, the sample transport distance will determine the total amount of sample delivered to the monitor. Whether this transport is done with a process pump, process pressure, stinger, or dedicated monitor pump, several factors must be considered. Chief among them is the representativeness of the sample.

That the sample does not change significantly during transport or that such change is not detrimental to the quality of the analytical results or to the reliability of the instrument is, of course, critical. In the sample transport step, the factor that is most likely to change drastically is temperature. Many processes operate at elevated temperatures, and the collection and transport steps can result in fairly severe decreases in sample temperature. Because many process streams applicable to FIA may be fairly concentrated salt solutions (for instance, plating baths), such temperature drops can result in solid material precipitating from solution – with subsequent catastrophic effects on the sample system! Temperature drops can also result in shifts in chemical equilibria, which results in a measurement bias. It is worth noting that sometimes the reverse situation occurs on a grab sample that is taken from the process and analyzed because such a sample may result in a substantially different value when compared to the on-line monitor.

Figure 10 Process sampling using a dedicated pump.
Finally, depending on the climatic conditions, cooling in transfer lines may be sufficient to actually allow the samples in the transfer lines to freeze or precipitate. Depending on the specific process and situation, it may be necessary to insulate or provide heat tracing to the transfer lines up to and including the SIA/FIA valve. Finally, the introduction of fast-loop piping (and other sample processing devices) will introduce various time lags in the analytical results. An exhaustive treatment of the possible sources of lag time is beyond the scope of this review, but such time lags must be considered for all parts of the sample handling system.

3.5.5 Sample Conditioning

Filtering is important because the presence of suspended solids is likely. One of the authors recalls an incident in an industrial plant in which a sample collection problem was found to be the result of a mop that had somehow entered the process stream piping! Even high-purity water-based process systems may have particulate matter resulting from piping or pump wear, so the addition of a filtration step is essential in on-line monitoring, and particularly so for FIA instruments because of the relatively small diameter internal tubing that is used. If the sample stream contains very low levels of particulate matter, it is possible to use in-line cartridge filters (available from many vendors), and simply change the filter element based on time interval or by measuring the pressure differential across the filter. However, if the levels of suspended particulate are higher, the cartridge-type filters will clog too frequently and result in unacceptably high maintenance requirements. The criteria for effective filtration must include not only how effective the particular filter is for removing particles above a certain size, but how long the time interval is between required maintenance (e.g. replacement or backwashing). The most useful type of filter is a cross-washed inertial filter (see Figure 11), because these types of filter yield the greatest reliability and require minimal maintenance.

Many sample streams either contain bubbles or dissolved species that will form gas bubbles upon removal from the process. The latter situation is usually attributed to the drop in pressure that occurs from the process stream pressure to the ambient (or nearly ambient) pressure at the instrument. If the initial quantity of sample to be analyzed is determined volumetrically (e.g. by the sample loop in an injection valve), the presence of bubbles will contribute to significant analytical errors, either by changing the size of the volume injected, or by outgassing to form bubbles after sample injection, with subsequent disruption of the normal dispersion patterns in the manifold or detector response. There are basically two approaches
to removing bubbles: (a) bubble separation based on gravity and/or wettability, and (b) membrane extraction. Gravity-based methods can handle very high quantities of formed gas bubbles, but are relatively ineffective at removing dissolved gases. The inverse is true for membrane extraction methods. Probably the best approach is to combine the two methods in series, with a gravity-separation device to remove the vast majority of formed bubbles, followed by a membrane device to remove any remaining dissolved gas (Figure 12). These two approaches are less suitable for cases where foam is present. Foams can be disrupted or broken by forcing the foam and liquid through a porous element, and then performing a gravity separation and membrane degassing downstream of the foam-breaker unit.

All of the above sample conditioning concerns apply to the determination of a liquid-phase analyte. Of course, FIA is used widely to analyze gaseous analytes as well. In such cases, an MSD is usually incorporated as the interface between the gaseous sample medium and the FIA liquid analytical stream. The gas-phase sample must be successfully collected from the process and physically transported to the instrument, subject to the same types of potential sample processing difficulties as described above for liquid samples (filtration, temperature regulation, pressure regulation, etc.).

Our discussion has attempted to address some of the challenges that are likely to be encountered when designing a process sampling system for FIA. A more exhaustive compilation is available that is applicable to the design of systems for the many other types of analytical instrumentation that are used in process monitoring.\(^{(32)}\)

**4 APPLICATIONS**

Since the late 1970s, process FIA has spread worldwide and is now in use by the chemical, petrochemical, refining, paper and pulp, mining, nuclear, biotech, food, pharmaceutical, brewing, wine, and aircraft industries. Several excellent reviews offer more details.\(^{(33–35)}\) The following sections describe examples of FIA process monitoring approaches in several of the major industrial application areas.

**4.1 Chemical (including Petrochemical) Refining\(^{(33–41)}\)**

An example of process FIA developed and implemented in the chemical industry is used to illustrate this application area. This application involved the monitoring of Fe\(^{II}\) in a process called Sulferox, an aqueous redox process for scrubbing H\(_2\)S from sour gas streams. A number of different technologies have been developed for this purpose, and they meet a great need because much of the natural gas in the world is sour, i.e. it contains H\(_2\)S from a few parts per million up to very high percentages. Obviously, this has to be removed before piping it to the customer.

The process chemistry involved an aqueous redox system in which an Fe\(^{III}\)–ligand chelate oxidizes H\(_2\)S to elemental S in an absorber, followed by removal of the elemental S by filtration in a continuously circulated stream. The absorber chemistry converts the Fe\(^{III}\)–ligand to an Fe\(^{II}\)–ligand; the stream is circulated to a regenerator where air oxidizes the ferrous chelate back to the ferric chelate, which is then returned to the absorber. The FIA process monitor was developed to monitor the level of the ferrous chelate before and after the regenerator. The FIA instrument is shown schematically in Figure 13, utilizing the well-known analytical chemistry of the formation of a colored complex between Fe\(^{II}\) and \(o\)-phenanthroline. This instrument was used on-line for several years, with process engineers relying on the information provided to optimize the Sulferox process behavior and chemistry. It was very useful to detect process problems before they caused an upset condition.

**4.2 Biotechnology (including Food, Fermentation, Pharmaceutical)\(^{(42–51,67)}\)**

It is significant that much of the on-line process monitoring instrument development activity since 1990 has
process instrumental methods

Figure 13 Diagram of an on-line FIA process instrument for monitoring the Sulferox process at Shell Chemical (BR = before regenerator, AR = after regenerator).

been in the biotechnology-related industries. Significantly, several companies have recently released on-line process monitoring products designed for this generally well-funded industry.

Mattisson and colleagues at Lund University recently reported the development of an on-line SIA process monitor for determining d-lactic acid in fermentation broth. The manifold design incorporates a broth-sampling interface and immobilized enzymes on porous glass beads in a minicolumn (Figure 14). The process monitor was tested with a quality control standard on every sixth cycle, and variations in the sample response were normalized (Figure 15). The cycle time was 3 min and the linear range of the method was from 1 to 25 mM – the authors note that the potential exists for automatic dilution by manipulating the sample volume as a function of the previous measurement. The extension of the linear range in this manner would provide flexibility to make the method very useful for the large concentration changes that are typically observed during cell cultivation. The 0.2 µm cellulose acetate membrane on the filtration inlet had to be replaced each day of operation because of the accumulation of cell mass. Reduced costs were realized by adding an expensive enzyme cofactor sequentially rather than continuously. The authors reported excellent agreement between their method and an off-line method that took considerably longer (10×).

4.3 Manufacturing

The application of process monitoring in the manufacturing sector is illustrated by describing a recent example from the aircraft industry. The chemical milling process involves the selective removal of metals from aluminum parts to reduce weight or change the shape. Parts are coated with polymer film, then the film is removed from the areas to be milled. The masked parts are dipped in hot concentrated caustic to rapidly dissolve the aluminum. The parts are removed from the caustic to measure etch rate and then re-immersed until the final dimension is achieved, followed by peeling of the masking polymer. The Boeing Company has recently developed an at-line SIA process monitor to determine the concentrations of NaOH, Al, and Na2S in the chemical milling solution by titration. The simple, inexpensive instrumentation has the additional advantages of using existing wet chemistry methods, suitability for metals, anions, and acid-base

titrations, low reagent usage, and flexibility to configure a single instrument for several methodologies.

### 4.4 Environmental

Process monitoring technology in general provides tighter process control which results in a more efficient process, fewer plant upsets, less off-specification product, and the minimization of waste. Waste minimization is often viewed as primarily an environmental issue, but it can also have a substantial economic pay-off. The following recent example of an at-line SIA process monitor for bioremediation of explosives illustrates this capability.

A spectrophotometric method based on SIA for the determination of 2,4,6-trinitrotoluene (TNT) in soil samples was recently reported. A schematic diagram of the instrument is shown in Figure 16. A derivatization reaction of the analyte with potassium hydroxide and sodium sulfite in a primarily acetone media was the basis of the chemistry of the method. This reaction was found to be sensitive to the amount of acetone in which the reaction took place. The percentage of acetone and water used in the reaction, sample and reagent volumes, mixing coil volume and reaction time were studied with the goal of obtaining optimal working conditions for the method. A percentage of 88% v/v acetone and 12% v/v water was used in the reaction. A study of the response of the method to other explosives (an interference study) demonstrated that the method is selective for TNT. Quantitative results from an analysis of contaminated soil samples were compared to those obtained using a standard HPLC method for TNT. The data showed that there was no statistical difference between the two methods. The precision of the method was established at 5.5% (for replicate soil samples). The limit of detection was 0.5 µg mL⁻¹ for aqueous samples and approximately 80 µg mL⁻¹ for 300 mg soil samples. The extension of the work to contaminated environmental water samples and the means by which samples could be preconcentrated using the sequential injection method were also developed.

### 5 STRENGTHS AND WEAKNESSES

The key strengths of process FIA include versatility, robustness, rapid response, high precision, high reliability, broad concentration range, and application to liquid and gas streams. Its versatility, in particular, provides process FIA with the potential of becoming a modular generic process monitor platform that could replace a large variety of different types of monitors currently in use.

In recent years, there has been a growing emphasis on more and better process analysis technology, and the driving force for this trend is increasingly intense global competition. The name of the game is the production of high-quality products at a minimum cost and in a manner that does not adversely affect the environment. This requires tight process control, and to control something well it is necessary to be able to measure it accurately and reliably. A well-designed and well-placed process FIA or SIA instrument can provide a substantial return on investment. The tighter process control provides a more efficient process, reduction of plant upsets, less off-specification product, and waste minimization.

There are, of course, many different types of process monitor technologies available to address these needs. In fact, it would appear that there are too many different types and this is the source of one of the problems that adds to the high cost of process monitors and the cost of maintaining them. For example, at a typical chemical plant familiar to one of the authors, there are 25 process monitors in place, and of these 25, there are 17 different types. Instrument technicians must be trained on all of the different types, and parts have to be stocked for all of them as well. Because of the great versatility of FIA, a significant number of these monitors could be replaced with a single, modular process FIA platform, simplifying training and maintenance. It may be possible in certain instances to perform more than one method on a single monitor platform, particularly for SIA. Some of the other important strengths of SIA are:

- versatility
- rapid analytical readout
- high reliability
- high precision and calibration stability
- broad concentration range
- low reagent consumption and waste generation
• multicomponent determination capability
• capability to monitor liquid or gaseous streams.

In the early years of process FIA, and this is still the case to a significant extent, a major barrier to the acceptance of the technique in plants was the fact that it is based upon wet chemistry. Plant operators and monitor support staff are very resistant to monitors based on wet chemistry methodologies. They do not like to handle solutions and waste or keep reagent reservoirs full. In fact, one of the major causes of downtime with on-line process FIA in plants is systems running dry because of the failure to refill reservoirs, even though that is generally a very simple task on the routine maintenance list.

As a result of this barrier, plants will, if at all possible, install conventional, well-established process monitor technology that does not involve wet chemistry, such as gas chromatography. The major reason process FIA has made inroads in on-line analyses is that in many important applications it can perform analyses that are impossible or very difficult with other process monitor technologies. If the payback was high enough, a plant would be willing to take a chance on FIA. An example is an application described in a 1994 publication involving on-line measurement of trace hydrogen cyanide. The prototype monitor monitored trace HCN in refinery gas streams from thermal and catalytic cracking units that contained high levels of hydrogen sulfide. Conventional process monitor technology, such as gas chromatography, could not perform this determination reliably on-line. A novel on-line FIA monitor provided a unique solution which could monitor hydrogen cyanide in these streams down to 50 ppb. Once process FIA has demonstrated its strengths in an application such as this, the barrier to additional applications generally fades.

Another of the strengths of on-line process FIA is its rapid analytical measurement, generally less than a minute for most system designs. Significant changes can occur on relatively short timescales (<30 min) for certain industrial processes. Other strengths include high reliability (typically >98% up-time), high precision (typically 0.5% RSD or better), and calibration stability (typically, calibrations hold for 1–14 days). Most on-line FIA monitors have built-in calibration checks which automatically recalibrate when they are out of specification. Another important strength is a broad concentration range, from a few ppb to several wt% for many instances. For concentrated streams, FIA can perform an automatic on-line dilution. FIA is generally used for liquid streams but, as already shown above for the HCN example, it can also be applied to gas stream monitoring in certain cases using MSDs.

Any critical discussion of the strengths of a process monitor technology should also include some discussion of its weaknesses or barriers to its implementation. These include:
• high-maintenance wet-chemistry technique
• difficult to identify noncorrosive chemistries
• difficult to efficiently introduce the sample
• few commercial suppliers of process FIA/SIA instrumentation.

One weakness that has already been mentioned is that FIA uses wet-chemistry technology and therefore requires some special attention by operators, such as ensuring that reagent reservoirs do not run dry. A dried-out FIA monitor generally requires a major effort to restore and re-equilibrate. Another barrier, also a wet-chemistry problem, is finding chemistries that are stable and benign. There is a rich resource of FIA chemistries to tap, but only a fraction of these are suitable for process FIA. The reagents must be stable for extended periods of time, and they must not be even slightly corrosive to FIA hardware. It can be surprising how many supposedly stable and noncorrosive reagents can, over extended periods of time, slowly corrode valves and pumps, or deposit decomposition products or precipitates that clog FIA lines.

Finally, a well-designed sampling system is critical to a successful on-line FIA, and if it is not included the system is very likely to fail. Although this is the case for most process monitors, it may be particularly true for process FIA because this technique uses narrow-bore tubing and thus is susceptible to particles and bubbles.

6 FUTURE DIRECTIONS

The 1980s brought a surge in innovation, development, and deployment of process FIA. Many large companies had multiple installations; Dow Chemical, for example, at one count had over 30 installed process FIA monitors. Because of the lack of commercially available state-of-the-art process FIA, pioneers in the field, primarily from the chemical and refining industries, developed their own technology in-house during this era.

The end of the 1990s has seen a new wave of interest and use of process FIA, and this is likely to grow into the new millennium. The technology is being embraced by a broader range of process monitoring applications than in the past. A number of factors are at work which account for the increased interest in the technique, in particular the commercial availability of advanced process FIA technology and technical support. The Center for Process Analytical Chemistry at the University of Washington has FIA as one of its research areas, and this has also had an impact on the awareness, development, and application of the technology.
A definite trend toward a preference of SIA over FIA, accompanied by an upswing in the development of new SIA strategies and technology, is likely to accelerate in the future. New components, such as 26-port selection valves and pulseless bidirectional liquid pumps, now allow users to take fuller advantage of the versatility of SIA. Combinations of SIA and FIA are also beginning to appear which simplify a complex FIA technique, and this trend will probably continue.\(^{(90)}\)

Future developments will be determined by present research efforts and the authors have noted several new application arenas. The research being conducted in these areas is performance-driven rather than of an esoteric nature. Some examples are given to illustrate this point.

- Some intelligence is currently built into many process FIA monitors, such as self-checking of calibration with decision to recalibrate if out-of-specification. Additional intelligence is likely to be developed and applied in future technology, such as if a measurement falls outside the calibration range to automatically dilute or take a larger sample, preconcentrate, etc.
- Researchers who are developing systems to be used in the environmental field are working at developing portable and robust monitors that can be left unattended for extended periods of time often in rather inhospitable environs. (e.g. at the bottom of lakes, on buoys, and in remote wilderness locations). The design advances used in these rugged instruments would also benefit the industrial process monitoring field.
- Complementary to the push for portability is a simultaneous effort toward miniaturization. Much work is ongoing in various quarters toward producing the laboratory-on-a-chip. Although such completely integrated devices potentially offer much enhanced capability in clinical and environmental analysis, their applicability to process analysis is unlikely to be as successful because of the vast variability in the nature of samples that are encountered. An approach of greater applicability would be integrated unit operations, in which small modules dedicated to specific actions (e.g. filtration) are developed which can be easily mixed and matched to accommodate sample-to-sample variability.
- MSDs, now commercially available but underutilized, are likely to become more widespread to simplify and enhance sampling systems for both liquid and gas streams.
- In situ generation of unstable reagents from stable solutions – either by reaction chemistry or by electrochemistry. This is, of course, already used in ion chromatography to generate eluants. The same approach can be used for many reagents, but particularly oxidants/reductants whose shelf-life is such that their use is normally precluded from process monitoring. The more reagent usage is decreased, the more important the shelf-life variable will become – the true barrier to implementation is not reagent consumption per se, but rather the maintenance interval that is required.
- There is an increasing use of embedded processors and this will continue as these systems become more robust and require less expert intervention.
- The extensive use of intranets, the internet, and extranets, as well as telemetry will increasingly place analytical results instantly in the hands of those who most need them. This will increase the use of analytical data and its conversion into useful information. The speed with which these data will be made available both by virtue of the proximity of the monitor to the sample source and the convenient transfer of analytical results will enable rapid and timely decision-making. We expect this capability to extend to compliance monitoring of industrial pollutant discharges as well.
- Also to be expected, using the same connectivity technology, is remote instrument diagnostics and maintenance. Part of the process of making instruments more robust will be in developing systems to allow remote diagnostics and even repair. No longer will the user be expected to understand the inner workings of the monitor; rather, the instrument manufacturer will be able to perform diagnostic tests from a remote location and then effect changes to the control system or even activate redundant back-up systems while defective components are returned for repair.

In summary, the future will see versatile, small-footprint, robust, and intelligent FIA/SIA monitors that will be deployed in an increasingly wide range of process applications.

ACKNOWLEDGMENTS

We thank Bruce Davis of Boeing for contributing an example of his group’s process monitoring research.

Infrared (IR) instruments have been in use as important measurement and analysis tools for process monitoring and production control for more than half a century. They range in complexity from the simplest filter-based photometers to opto-mechanically complicated devices, such as Fourier transform infrared (FTIR) instruments. Simple nondispersive infrared (NDIR) instruments are in common use for systems where one to a few main analytes are involved. For more complex measurement situations it is necessary to record more spectral information, and often full-spectral analyzers are used. Of the main analytical instrument techniques, IR analysis is the most versatile, where all physical forms of a sample may be considered – gas, liquids, solids and mixed phase materials. A wide range of sample handling options exists, and many of these may be adapted to either near-line/online production control or on-line process monitoring applications. Instrumentation used within a manufacturing environment usually requires special packaging to protect the instrument from the environment, and to protect the operating environment from the instrument. This places special constraints on the way that an instrument is designed and the way that it performs. Often, it is necessary to utilize special technologies, normally not required for laboratory instruments, to meet the performance objectives. For most practical installations within a production environment it is a normal requirement for the final instrument to comply with local manufacturing and electrical safety codes. The range of applications of IR spectroscopy is extremely broad and the technique can play an important role in virtually all industries for manufacturing quality and production control, and for environmental monitoring.

1 INTRODUCTION

Process IR analysis and the associated instrumentation are very broad and diverse topics that can be defined in a number of different ways. The instrument may be viewed as something very simple, such as a rudimentary measurement device, or as a complex, multifunctional measurement tool. In the end it depends on the application and the needs of the end-user. For many traditional applications the IR instrument merely provides a single-point measurement, and as such may be considered to be acting as a sensor, similar in context to a pressure transducer or a thermometer. In such cases one is normally not considering the measurement to be a true spectral measurement. Over the past two decades, there has been a trend to use analytical-style instrumentation for process measurements – for analysis, monitoring and control. This has resulted in the use of the term process analytical instruments (PAI). Process spectrometers are an important class of these instruments, and instrumentation used for vibrational spectroscopy, in particular IR spectroscopy, accounts for a significant number of the systems that are implemented for process measurements (both on-line and off-line).

For nearly half a century, vibrational spectroscopy, initially in the form of mid-IR spectroscopy, has been featured extensively in industrial analyses, both for quality control (QC) and process monitoring applications. Next to chromatography, it is the most widely purchased instrumentation for these measurements and analyses.

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd
Spectroscopic methods in general are favored because they are relatively straightforward to apply and to implement. Furthermore, a single IR instrument, in a QC environment may serve many functions, whereas chromatographs (gas and liquid) tend to be dedicated to only a few methods at best.

Historically, the first industrial applications of IR spectroscopy were for quality and production control in the petrochemical industries, primarily for the analysis of fuels, lubricants and polymers. Early instruments were configured solely for mid-IR absorption measurements. Over the years, the other important vibrational spectroscopy techniques, namely Raman and near-infrared (NIR), have grown in popularity. Raman, as an experimental concept, was understood as early, if not earlier than mid-IR. However, there were significant difficulties encountered in its early implementation, and as a result, it has only been in recent years that it can be considered as a viable technique for process-related applications. Early on, NIR was never really considered to be an analytical technique with any practical value, and in fact it was originally addressed as an extension of the visible spectral region, rather than the IR. It was not until work was performed in the 1970s with agricultural and food products that the value of this spectral region was appreciated, in particular for quantitative measurements. Today, the value, functionality and benefits offered by all three of the major vibrational spectroscopy techniques, IR, both mid-IR and NIR, and Raman, are largely uncontested.

Taking into account all of the techniques, virtually any form of sample can be handled, including gases, aerosols, liquids, emulsions, solids, semi-solids, foams, slurries, etc. This is also a major factor when comparing chromatographic methods to spectroscopic methods. In a traditional QC environment, a single spectrometer can be configured to handle a wide range of sample types with a choice of suitable sample-handling devices. The nature of the sample plays an important role in the decision process, and in many ways it is the most demanding element for consideration when assembling a system for an industrial application. This is especially the case if we extend the application to become a full on-line process measurement, where the sample extraction and conditioning can be more expensive than the spectrometer itself.

Since the late 1980s, IR spectroscopy, both in the forms of NIR and FTIR spectroscopy, has been hailed as a major growth area for process spectroscopy. This view assumed that the areas concerned were outside of those covered by traditional laboratory instruments. Overall, this has been very difficult to define in terms of where the boundaries between the laboratory and the process start and end. Some of the confusion arises by the term “process analysis” itself. In the most liberal form, it can be considered to be any analysis that contributes in the manufacture of a product. This can range from the quality assessment of incoming raw materials, to the control of the manufacturing process itself, and finally on to the examination of the final product. How this is viewed tends to be industry dependent.

With traditional thinking, process analysis provides feedback to the process control system, thereby ensuring that the product is manufactured correctly. However, in some industries the final quality of the product is the most important controlling parameter, and this requires that analytical controls be placed at all key points in production. Examples here include high-tech manufacturing, such as in the semiconductor industry, and specialty or value-added chemical production, such as in the biotechnology and pharmaceutical industries. In the petrochemical and petroleum industries, which tend to use continuous processes, information that helps to control the process itself tends to be the most important attribute provided by the analysis. Considering all these factors and requirements, it is important to review how the analysis is physically implemented, giving rise to terms such as on-line, off-line, near-line and at-line. In general, these terms should be self-explanatory. However, there are at times some confusion, especially when considering the best way to implement an analysis. Overall, the deciding factors tend to be the turn-around time required for the analysis and the cost and ease of implementation.

In the context of industrial applications, as applied to this article, it is necessary to address the instrumentation as a package or a system. Dependent on the requirements of the analysis and the technique selected, a system can consist of several key components:

- the instrument, which contains a source, analyzing component, detector, analyzer control electronics and data handling (internal or external computer);
- sample handling and interfacing;
- sample extraction and conditioning (mainly a requirement for on-line, continuous monitoring systems);
- environmental enclosure (for hazardous environments); and
- communications to the user/operator and to the process control computer.

Each of these can become a major subject for discussion, and a detailed coverage of all of these items is outside the scope of this article. However, it is intended that this article will provide the reader with an overview of the instrumentation and technology that is available and in common use for process-related measurements featuring IR spectroscopy. Also, general discussion will be provided regarding both the implementation and applications of current instrumentation. It must
be understood that IR spectroscopy does not provide answers for every application, and other techniques, including a technique such as Raman spectroscopy, may provide a better solution. Where appropriate, side references will be provided, in context, to the use of the other vibrational spectroscopy techniques.  

2 THE BASICS OF INFRARED SPECTRAL MEASUREMENTS

Although IR spectroscopy and IR instrumentation are covered elsewhere in this publication, it is important to define here some of the basic principles of the measurement. This is of particular importance for instruments dedicated for specific applications because it helps to assess the technology and materials that are optimum for a final measurement system. It is important to define the measurement techniques in terms of their spectral range, the units and conventions that are used, and their general utility. While this may seem obvious or basic in context, the boundaries must be defined when discussing measurement technologies and their application in a process environment. In other words, it is essential to match the characteristics of an individual technology to the performance required for the target application.

Initially, the term IR (in the context of instruments) was applied to the spectral region from around 2.5 μm to approximately 16.5 μm. At the time, this was dictated by the optical systems in use, which were based originally on sodium chloride optics. Later, the range was expanded down to 25 μm, and today this is generally accepted as the mid-IR region (2.5 to 25 μm). Instruments can provide measurements out to longer wavelengths; this region is known as the far IR, and generally it has limited utility for routine or industrial applications. Traditionally, an energy scale expressed as wavelength, in micrometers, was used, and is still used in certain contexts. Analytically, a frequency scale, which is linked to molecular vibrations, based on wavenumber (cm⁻¹), is preferred. In the mid-IR region (4000–400 cm⁻¹), the most dominant absorptions are associated with the fundamental vibrations of component chemical bonds from functional groups, the backbone structures and molecular fragments of the material under study.

The definition of NIR is in some ways slightly more complex, dependent on context, and also when factoring in analytical and practical issues. By convention, it is the spectral region between the end of the visible, approximately 700 nm (0.7 μm) and the start of the IR 2500 nm (2.5 μm). Traditionally, because of the origin and type of instrumentation used, the units of wavelength are used. However, in recent years, mid-IR instruments have been extended into the NIR region, and in such cases wavenumber scales are sometimes used, ranging from around 14 000 cm⁻¹ to 4000 cm⁻¹.

From an analytical perspective, the information content of the NIR varies throughout the spectral region, and different regions are used for different applications. In all cases, the measurements utilize absorptions associated with overtones and combinations from the fundamental vibrations that occur in the mid-IR region. For the most part, these regions are dominated by absorptions from the “hydride” functionalities – C–H, O–H, N–H, etc. Three groups of information are observed, and these are nominally assigned to first, second and third overtones of the hydride fundamentals, combination bands, plus some coupling from vibrational frequencies of other functional groups. A progression through the three main overtone regions, from first (longest wavelength) to the third (shortest wavelength), has a significant practical impact in regard to the order of magnitude of the intensity of the signal that is measured. The first overtone being at least one order less intense than the fundamentals (mid-IR), and the second and third each being additional orders less than the first. This impacts the practical nature of the measurement because of the increase in effective pathlength that is required to gain adequate spectrum intensity, plus it influences the success of specific modes of measurement – reflectance vs transmission.

From a technology aspect, relative to the actual measurement, the practical spectral range is impacted by the major components of the instrument – source, detector and energy analyzer. Detectors often have the biggest impact, where some detectors work best in the first overtone and the top-end of the mid-IR (such as InAs and the lead salt detectors), others operate in the first and second overtone regions (such as InGaAs), and others only function in the third overtone region (short-wave NIR, such as silicon and charge-coupled device (CCD) arrays). All of the above issues – information content, measurement mode, and the photonics involved, have a significant influence on what is practical for a particular NIR measurement, and in turn, these can impact a user’s perception of the definition and utility of NIR. Finally, one minor issue is that in certain contexts, such as in sensors and certain factory measurement systems (such as moisture meters) the term IR is commonly used even though the measurement is made in the NIR.

Both mid-IR and NIR are established in areas where each one provides unique attributes for application in both QC and process/production measurements. There are many factors that determine the selection of the preferred technique for an application, and these can range from subjective issues, such as personal bias to practical issues, such as ease-of-use, sensitivity, accuracy, size and...
PROCESS INSTRUMENTAL METHODS

cost. One or more of these factors influences the manner in which instruments are applied today. To a large extent this is impacted by the conventional approach that has been adopted for the development of instrumentation, that is, an industrial analyzer tends to evolve from a traditional laboratory instrument. Laboratory instruments, by nature, are flexible and multifunctional. The manufacturers intend that an instrument be used for as many different applications as possible. Although this is a benefit in a research-oriented environment, it can be a handicap in production-oriented instrumentation. An analyzer that has evolved in this manner is often an excellent concept model, but is not ideal as a final dedicated analyzer. For many applications, a “traditional” style of instrument is overkill, and it is important to take a “keep it simple” or a “good enough is OK” attitude for a practical solution.

3 INSTRUMENTATION BASICS

As indicated earlier, an optical spectrometer can be separated into a set of basic elements: radiation source, energy analyzer or encoder, detector, data acquisition and control electronics, and computer, consisting of hardware and software, with an appropriate user interface (keyboard/control panel, display and graphics). Also, as noted, consideration of the sample, sampling interface and the associated optical geometry are essential if a successful implementation is to be accomplished. Figure 1 provides a typical schematic for an optical spectrometer with all the key elements in place. All spectrometers conform to this configuration, with subtle variations, dependent on the sample and mode of measurement. For example, in emission measurements, the sample is in essence the source. As shown, the configuration implies that the radiation passes through the sample, and this only applies to transmission measurements. In a reflection configuration, the surface of the sample is illuminated, and the reflected radiation is collected from the same side. One other variant of the theme (as illustrated) is the remote sampling approach where the sample is located away from the main spectrometer, and the radiation to and from the sample is carried via optical fibers or some form of light conduit.

There are several measurement techniques that can be considered for use in IR-based instrumentation, and these are summarized in Table 1. Some of these techniques are classical, as in the case of optical filter-based instruments and scanning monochromators. Others, such as AOTF, have been considered for 10 or more years, but only now are being utilized to any extent, and currently these are limited to NIR measurements. References to the use of lasers go back more than 30 years, and a few of the most recent applications can be considered as cutting-edge technologies. Their use in the past has been limited by the availability or the cost of the technology involved (examples being diode and tuneable lasers, and certain types of detector arrays).

3.1 Component Technologies

This section will be restricted to discussions concerning source and detector technologies. There are other important technologies to consider, especially in the area of data acquisition, control and computer technologies. This is a rapidly changing area, and if viewed generically, serves all forms of instrumentation. Some instrument companies still develop their own proprietary electronics and computer systems. Reasons such as performance optimization, packaging and the need for compliance with certain safety and electronics regulatory codes are often cited. In the latter case, a systems approach is required, especially when attempting to meet the code or performance requirements for compliance with European Certification (CE) mark or electrical and fire safety codes such as National Fire Prevention Association (NFPA) and Cenelec. Often, off-the-shelf electronics can provide the necessary performance characteristics for most applications, and their use can eliminate large expenses related to product development, plus the associated time delays. Furthermore, except in extreme circumstances, nobody would attempt today to develop a custom-built computer.
system for a commercial instrument. It is feasible to bring an instrument concept to market for most application areas featuring commercially available components. Only the photonics-related components are addressed in this section because they are the only application-specific components.

The selection of source and detector are interrelated, because obviously the detector must be effective for receiving energy from the source. However, the exact nature of the source is also dependent on the type of sample(s) under consideration, the intended optical geometry, the type of measurement technique, and the final desired performance. In other words, sufficient light must reach the detector to provide a signal-to-noise performance consistent with the required precision for the measurement. This is assuming, of course, that the detector is well matched, optically and performance-wise, and is also capable of meeting the performance specifications.

3.1.1 Polychromatic or Continuum Sources
Most optical spectral measurements, where the measurement of multiple wavelengths is required, will feature some type of polychromatic light. There are a few potential exceptions here, such as tuneable laser sources and source arrays. In such instances, the source is effectively “monochromatic” at a given point in time. These sources will be covered separately under monochromatic sources.

Almost by definition, sources intended for IR studies are thermal sources, and feature some form of electrically heated element. There are essentially two types of polychromatic source: the open element source and the closed element source. The latter is effectively a light bulb, with the quartz halogen lamp being one of the most important, and is commonly used for NIR applications. This high-temperature source operates around 3000 K and its energy distribution is well optimized for the NIR spectral region. The source also provides a significant amount of energy in the mid-IR region, but the quartz envelope of the bulb does not transmit energy much below 5.5 to 5.0 µm. A variant on the “light bulb” is an enclosed electrically heated element within a standard electronics package (such as a TO-style (i.e. packaging style) can, as used for detector packaging). The unit is sealed with a low-pressure atmosphere of a protective inert gas, such as nitrogen, by an IR transmitting window, such as potassium bromide (KBr), zinc selenide (ZnSe) or germanium (Ge). The thin filaments used in bulbs and bulb-like sources have a low thermal mass, and this provides the opportunity to pulse the source.

The other form of polychromatic source, used widely in most conventional laboratory-style IR instruments is the exposed, heated element. Various designs have been used, with metal filaments, made from Kanthral® and Nichrome, being simple solutions in lower cost instruments. They tend to be mechanically fragile, especially when subject to vibrations while hot. Electrically heated ceramic sources are popular, and these are more robust and reliable than simple wire sources. These include sources made from silicon carbide, with the Globar® and the Norton sources being common examples. The Norton source is used extensively on modern low-to-medium cost instruments and for instruments used for process applications. It is a simple, rugged source, which was originally used as a furnace igniter. Typical operating temperatures are in the 1100–1300 K range, with the Globar® being an exception at around 1500 K. This higher temperature is seen as a benefit for low light throughput applications, but it can pose thermal problems relative to heat dissipation and sample heating, with the potential for sample degradation.

Most detector systems require that the IR beam be modulated. Modulation of the source energy provides a means of differentiating the measured signal from the ambient background. One of the traditional approaches is to use some form of mechanical “chopper”, usually in the form of a rotating sector wheel, which modulates the beam by blocking the radiation in one or more sectors during a rotation. An alternative approach is to pulse the source by modulating the electric power to the source, thereby eliminating the need for any form of mechanical chopping device, an important factor in dedicated and process-style instruments. This approach is only practical for low-mass sources, such as wire filament or light bulb style sources described above. Certain measurement techniques, such as interferometry, as used in FTIR instruments, modulate the radiation as a consequence of their mode of operation, and do not require independent modulation of the source.

3.1.2 Monochromatic Sources
The most common “monochromatic” source is the laser. Today, this type of source is becoming more popular for a wide range of spectral measurements – in both instruments and dedicated chemical sensors.

Tuneable lasers have always been the dream of spectroscopists. The concept of having a small, high-powered monochromatic IR light source that can be tuned rapidly to other wavelengths would seem to be the ultimate for many applications. Today, there is partial success in this area, and this depends on the application and the spectral region under consideration. Certain solid-state lasers are tuneable over narrow wavelength ranges in the NIR and long-wavelength mid-IR. Tuning is accomplished on a stepwise basis by temperature or pressure programming the device. While the tuning range is typically very small, often no more than a few
nanometers, it is sufficient to be able to scan through the narrow line spectra of certain gas species. The devices are quite useful for the measurement of low concentrations of specific gases and vapors. An array containing several laser elements is feasible for handling gas mixtures. Tuneable laser sources have been used for monitoring species such as hydrogen fluoride, light hydrocarbons, and combustion gases.

Other noncontinuum sources, which are effectively multi-wavelength “monochromatic” (because of line width) or multiple line sources, such as gas discharge lamps, have been used, and are often considered to be useful for calibration purposes. Another novel source, which is polychromatic in character, but is monochromatic or species-specific in behavior, is the molecular equivalent of the electrodeless discharge lamp. The source utilizes a low-pressure gas, the same as the analyte species, and the molecules of the gas are excited within a radiofrequency field. The excitation produces molecules, and the source emits radiation in the IR region at the characteristic wavelengths of the molecular species. In this manner, a spectrometric measurement system can be developed where the analytical wavelengths of the analyte are identical and resonantly coupled to that of the source – comparable in nature to an atomic absorption measurement. This is similar in concept to a correlation filter photometer (see later), except that the source provides the filter function. Commercial instrumentation has been developed, based on this technology, for medical applications, but it has potential for use in other applications, such as the measurement of combustion gases.

### 3.1.3 Single Element Detectors

Traditional spectrometers feature single element detectors. Generally, such instruments utilize only a single detector. Exceptions are certain analyzers that are equipped with detectors dedicated to a single wavelength, either within a spectrograph arrangement, or with dedicated optical filters. The selection of detector is dependent on the spectral region being covered. There are two main types of detector in use – thermal detectors and photon detectors. In the mid-IR region thermal detectors are used for most routine applications. The most common thermal detectors are the pyroelectrics, such as DTGS (deuterated triglycine sulfate) and lithium tantalate. Lithium tantalate detectors are used widely for low cost sensing devices (including fire alarms), where the detector element can cost as little as $10 (US). They are also used in filter-based instruments and in low-cost scanning instruments. Most routine scanning instruments feature the more expensive and more sensitive DTGS detector, which is somewhere between one and two orders of magnitude more sensitive than lithium tantalate, depending on implementation.

Thermal detectors by nature have a relatively slow response, and are not efficient for fast data acquisition rates. Also, the same applies in certain experiments where there is low energy throughput, as in some reflectance measurements, high-resolution gas analyses, certain fiber optic-based measurements, or where a light-pipe conduit is used for interfacing an instrument to a sampling point. Traditionally, for such applications featuring low light levels or high-speed acquisition, the MCT (mercury–cadmium–telluride) detector is used. This photon responsive detector is operated at sub-ambient temperatures, usually cryogenically cooled to liquid nitrogen temperatures. When operating with liquid nitrogen cooling it is necessary to manually fill a Dewar cold-trap. These normally have an 8-h capacity, but extended fill versions are available, providing up to 24-h usage. Obviously, the requirement to manually fill the Dewar, and the limited capacity, pose limitations on the usage of this style of detector. Although a commercial system exists for autofilling the Dewar, the detector tends to be limited to laboratory-based applications. This type of detector system has been used in a few industrial applications, mainly for high-resolution gas monitoring, chemical reaction studies and specialized semiconductor analyses.

Alternatives to cryogenic cooling include thermoelectric cooling (Peltier devices) and thermo-mechanical cooling (Sterling coolers, recirculating micro-refrigerators and Joule–Thompson (J–T) coolers). None of these solutions are ideal: Peltier coolers have to be operated as three- or four-stage devices, Sterling engine coolers have limited mechanical lifetimes, and J–T coolers often exhibit vibrational coupling problems. Of these, the thermo-electric coolers are often the most straightforward to implement. However, they do not achieve liquid nitrogen temperatures (77 K) which are necessary in order to gain optimum sensitivity. Typically, the devices cool down to about −75 °C (200 K). This limits the spectral range to a band width of around 1000 cm⁻¹ in the mid-IR and reduces the detector’s performance closer to the DTGS detector. However, the high-speed data acquisition benefits of the detector are retained. Both the three- and four-stage Peltier cooled and Sterling cycle engine cooled MCT detectors have been used for process and environmental monitoring applications with dedicated FTIR instruments.

With the transition into the NIR, the choice of available detector types increases, dependent on the application and the measurement range that is required (as indicated earlier). They are all solid-state photodiode-style detectors, and they range from the traditional lead salt (PbS and PbSe), germanium and silicon detectors, to binary
and tertiary detectors, such as indium arsenide (InAs), gallium arsenide (GaAs), and indium antimonide (InSb) and indium gallium arsenide (InGaAs). The most popular selections are the lead salts, InGaAs and silicon.

3.1.4 Array Detectors

Until recently, the only detector array elements in common use were the silicon photodiode arrays, and these were initially used for UV/VIS measurements, and later with extended performance into the short-wave NIR. These and CCD arrays increased in availability, thanks to the explosion in the electronic imaging market (fax machines, scanners, digital photocopiers, video and digital cameras, etc.). In recent years, dispersive Raman spectroscopy has gained ground significantly thanks to the availability of high-performance CCD cameras. Recently, there has been a noticeable increase in the commercial availability of miniature spectrometers covering the UV/VIS/NIR spectral region. These are based on relatively low-cost CCD array detectors (with a width as high as 2048 pixels), providing spectral coverage from as low as 190 nm in the UV to 1100 nm (1050 nm) in the short wave NIR. These systems can be purchased for as little as $2000 (US), including provision for fiber-optic coupling.

InGaAs detector arrays operating in the mid-range NIR, developed originally for military imaging applications, have been introduced during the past 5 to 6 years for spectral applications. However, until very recently, these devices lacked consistency (pixel-to-pixel) and were very expensive, even for 128 and 256 element arrays. Note that the number of elements has a direct impact on the relative spectral range and/or the spectral resolution that can be used. Recently, arrays based on lead salts (lead sulfide and lead selenide) have been introduced, and these have provided extended performance into the mid-IR region – down to around 4 µm (2500 cm⁻¹) – which is adequate for measuring the “hydride” fundamental (O=H, N–H and C–H) vibrations.

MCT arrays have been used by the military for night vision imaging for many years, and some detector vendors will custom-fabricate these detector arrays. Again, the price of such custom-designed and produced devices is cost-prohibitive, unless there is the opportunity for mass production. So far, a market does not exist for such mass-produced devices, and so their general availability for routine or process instrumentation is currently out of the question. Furthermore, the need for cryogenic cooling has to be considered.

Array detectors operating in the mid-IR spectral region, like tuneable laser devices for the same region, have been a desire for instrumentation producers for some time. It has been known that detector array devices based on DTGS and other pyroelectric materials, including micro-machined devices, have been developed for military applications. Such detectors are expected to become commercially available in the next few years, and these are anticipated to have a significant impact in process-related applications.

4 PROCESS ANALYTICAL INSTRUMENTS

The classical definition of a PAI analyzer is a totally integrated system, implemented on-line, and made up of some or all of the following components:

- instrument, sensor or measurement technology;
- sampling system (if needed);
- signal acquisition and data handling; and
- communications with a process computer.

Often, the term process analyzer is taken too literally, and sometimes nonclassical approaches fail to be considered as practical examples. For example, in the semiconductor industry, traditional analyzers are used as on-line gas and water sensors, but product analyzers are seldom viewed as process analyzers. The semiconductor wafer, the product, is monitored at various stages of the process, effectively in-line or off-line by FTIR analyzers. It should be pointed out that FTIR is the only accepted method for the QC of the product. In a process that can involve up to 32 critical steps, and where a high yield at each step is essential, it is unreasonable not to consider FTIR as a true process analysis tool. The application is made practical by the use of high-precision wafer-handling robotics.

The traditional industry focus is often on IR photometers, used on-line, and these are mainly used in the environmental market (stack gas and ambient air related applications). There are also a relatively large number of on-line process stream analyzers for liquids and gases (mid-IR) and solids (NIR), that feature either filter (discrete) or full-spectrum analyzers. Many industries are rethinking the role of process analyzers, and applications featuring “near-line” or “at-line” are now considered to be appropriate especially when the timescale does not require real-time measurements. Many of these analyses are just as legitimate as process measurements as the direct on-line analogues. However, the cost of implementation is often much lower. The final mode of implementation is usually based on the nature of the process, the needs of the end-user, the overall economics, and the required speed of analysis.
4.1 Commercial Process Instrumentation: Chromatographs

While the focus of this article is on IR spectroscopy, it is important to appreciate that spectroscopy is not always the preferred technique for process measurements. To place it in perspective, it is first important to view the technique that has become the process analytical method of choice for many process engineers for nearly 20 years. Process gas chromatography (GC) forms a mainstay for PAI systems in the petrochemicals and chemicals industries, being used for monitoring and control of both gaseous and liquid material production. There are pros and cons – the advantages of GC are that it is a separations technique, it works well for mixtures, and it provides an excellent measurement dynamic range – from ppb/ppm to percent levels. It is also well established, and plant engineers are generally comfortable with the technique. It tends to be a standard for PAI systems throughout most of the petroleum and chemical industries, and it is often the technique of choice, merely on the grounds of familiarity. On the negative side, it is limited to low boiling liquids and gases, and it can have a high cost of maintenance. Sample interfacing and sampling systems can also be an issue, again dependent on application and material type.

Traditional IR process analyzers (filter-based instruments) fail to provide a feasible alternative to GC for most applications. However, modern full-spectrum analyzers, in particular FTIR analyzers, combined with multicomponent analysis software (such as classical least squares and multilinear regression techniques), can provide a good practical alternative for certain applications. Furthermore, removing the need to separate the sample expands the area of applications to mixtures that include nonvolatile and/or thermally labile compounds.

4.2 Commercial Process Instrumentation: Photometers and Spectrometers

As previously noted, spectrometers fall into several categories, from simple optical photometers (single filter devices) to relatively complex full-spectrum devices, such as FTIR instruments. It has been stated, by some process engineers, that there is a preference for using optical methods of measurement rather than chromatographs because of perceived lower maintenance and ease of implementation. However, this may be both system- and application-dependent.

Single component analyzers, in the form of NDIR analyzers, have been in use for decades for both industrial and environmental monitoring applications. These are usually simple filter-based analyzers featuring one or more wavelength specific devices, customized for a specific analyte, such as CO, CO₂, hydrocarbons, water (moisture), etc. Such instruments are inexpensive and easy to maintain. If one reviews the market in terms of the usage and where the most analyzers are being purchased, this class of instrument, both for mid-IR and NIR measurements, is by far the most popular.

To some extent, these simple filter-based instruments are limited to applications where there is simple chemistry, and where the analytes can be differentiated clearly from other species or components that are present. In many ways, these analyzers are viewed as simple sensors or even meters, and are not viewed by the analytical instrument community as true instruments. During the past 10 to 15 years, a new focus on instrumentation has emerged based on more sophisticated technology, and is considered to be a direct evolution from laboratory instruments. To some extent, this started with an initial interest in NIR instruments. In this case, it was demonstrated that because of the nature of the information obtained in the NIR spectral region, that an analyzer capable of measuring multiple wavelengths and preferably a full spectrum was most desirable. From this, the entire market for NIR instruments developed in the late 1980s through to the 1990s for scanning NIR instruments. In some cases filter instruments were used, but because of the need to measure multiple wavelengths, the instruments became more complex than traditional filter photometers.

In parallel to the development of full-spectrum NIR analyzers, interest was developing in the other area of mid-IR. By the mid-1980s, FTIR was becoming accepted as the de facto method for measuring the mid-IR spectrum in a laboratory environment. However, FTIR was considered to be too complex and too fragile to have any utility on the factory floor or on a process line. To some extent this was true based on the state-of-the-art of the technology used in the laboratory-based instruments. Some pioneers in FTIR managed to prove the concept with modified laboratory instruments. However, after a few false starts, it was recognized that it was not practical starting from an instrument designed for the laboratory environment. At least two companies, starting around the mid-1980s, and later others, decided to focus on industrial applications, and designed instruments for operation in more demanding environments.

4.2.1 Photometers

As noted, the largest class of IR analyzer is the filter photometer. These are one of the oldest forms of PAI, with generally simple construction, and are sold at relatively low cost. In the simplest form they consist of a source, a filter, a sample cell and a detector. They are usually single channel devices, and consequently function as a single beam instrument. Miniaturization has lead to the production of small, integrated devices that essentially behave as single sensors.
case, the filter, the source and the detector define the analytical spectral region. Most filters are bandpass or correlation (gas-based), dependent on application – the latter being used for specific low concentration gas applications. Most traditional process photometers are configured for single component measurement, with the most basic featuring a single filter selected to transmit at the analytical wavelength/frequency, as indicated in Figure 2.

With this form of instrument, the baseline is established with a zero sample, and the span (range) is established with a maximum value sample. Although the electronics are simple, and designed for stability and low noise, it is usually necessary to establish zero and span settings on a regular basis, often daily. This can necessitate a calibration overhead on even the simplest photometer. The reason for this comment is that although filter photometers may seem to be simple and low cost, ownership can be more complicated in terms of the need to calibrate and its associated costs.

Conventionally, the first thoughts are towards simple measurement systems featuring one or two optical elements with the simple construction as stylized in Figures 2 and 3. In practice there are many forms of filter device that can be used. These include simple single wavelength filters, clusters of filters or filter arrays (multiple wavelengths), correlation filters (with the analyte), continuously variable filters (circular variable filter, (CVF) and linear variable filter, (LVF)) and tuneable filters (such as the AOTF).

The use of continuously variable filters is not new, and scanning instruments featuring single element detectors have been in use for at least 25 years. Likewise, clusters of filters or filter arrays have been used for NIR instruments and some mid-IR instruments with single detectors. In all cases, a mechanical device is required to drive the filter assemblies. The reproducibility and reliability of these devices is cause for concern, and often limits the performance and utility of these approaches. Filter clusters and continuously variable filters (such as an LVF) can combine well with array detector devices, as indicated in Figure 4. Such a combination can lead to a very compact instrument for simple transmission measurements on liquids or gases, and eliminates the mechanically related problems associated with moving parts.

AOTF devices,\(^{(10,11)}\) which tend to be limited to the visible and NIR spectral regions, also overcome the mechanical problems associated with multi-wavelength filter instruments, and feature only a single element detector. They provide the benefit of rapid spectral scanning, with a single full-spectrum acquisition in about 200 ms. An alternative mode of operation is to step the device to specific wavelengths. This is an extremely rapid process, and emulates a multi-wavelength filter system, with near-instantaneous output at each wavelength. With these features, these devices would appear to be ideal for rapid NIR measurements. However, they have only received partial acceptance, primarily due to a relatively high cost of the instrumentation, and wavelength calibration and stability issues.

The largest application segment for traditional filter photometers is for combustion gases analysis (for CO, CO\(_2\), hydrocarbons, SO\(_2\), etc.). Other major areas of application include the petrochemical industry, with natural gas and other hydrocarbon process gas streams being important applications. The remainder of the applications are for specialized process analyses, featuring both gas and liquid applications. As measurements become more complex, in general, the more advanced
filter-based (LVF and AOTF) analyzers, or full-spectrum FTIR or NIR instruments are considered to be attractive solutions, both in terms of cost and versatility. It is anticipated that this situation may change once array-based systems become available. In such cases, the combination of filter and detector arrays, or LVF devices with arrays, could lead to lower cost, more versatile analyzers.

4.2.2 Monochromators and Polychromators

For many years, the standard configuration for optical spectrometers for mid-IR and NIR featured a scanning monochromator. These included a single source and detector, with a mechanically scanned dispersion element in combination with optical slits for spectral line separation. In many systems, both the dispersion element (a refracting prism or a diffraction grating) and the slits were driven mechanically by relatively complex mechanisms. Although this arrangement functions adequately in a laboratory environment, it is not always ideal for operation in a heavy industrial setting. Reliability, calibration, and overall performance (or lack of) have been factors that have limited the use of monochromators. Today, a few of the commercial NIR instruments still feature monochromators and all standard commercial mid-IR instruments now feature interferometers (FTIR).

Monochromators, by definition, provide energy of one wavelength (or a few wavelengths) at a time. In other words, the devices scan through the spectrum sequentially. A polychromator allows multiple wavelengths to be measured simultaneously. This arrangement is used in instruments that feature detector arrays, and this principle is illustrated in Figure 5. In this simple example, a concave diffraction grating is featured, usually a holographic element, and this splits the energy spatially into the analytical wavelengths and provides the necessary imaging on the array. The advantage of array-based spectrometers is obvious, based on the fact there are no moving parts, providing the mechanical and wavelength stabilities necessary for highly reproducible measurements in a factory or plant environment. Currently, several commercial instruments, many in a compact form, are available based on this concept, featuring arrays that operate in the NIR. The longest wavelength version of these, based on a lead selenide array, does cover the top-end of the mid-IR region.

One technique that can utilize the output from a monochromator, and can provide some of the benefits of multiplexed data acquisition, is known as a Hadamard transform spectrometer. This type of instrument can in fact feature either a monochromator or a polychromator (equipped with a detector array). Today, such instruments are available as custom-made devices, but none have been commercialized.

4.2.3 Interferometers

By the mid-1980s most of the mid-IR measurement technology moved away from dispersive instrumentation (monochromator-based) to interferometry, with the widespread introduction of FTIR instruments. These instruments provided the performance and flexibility that had been in demand for mid-IR. The basic elements of an FTIR instrument, featuring a Michelson-style of interferometer, are illustrated in Figure 6. Critical elements in this style of instrument are the beam-splitter and the two mirrors (one fixed the other moving). Because the system requires the measurement of an optical interferogram, generated at high optical precision, from this mirror–beam splitter combination, the mechanical tolerances on the construction are extremely demanding.
The drive mechanism used for the moving mirror assembly (which provides the spectral scanning) has to be critically controlled, and must be made impervious to external interferences, such as vibration. In the mid-IR region, the beamsplitter is also an environmentally fragile element. This optical element, which is usually constructed from a hygroscopic material such as potassium bromide (KBr), serving as the main support substrate, has to be prepared to high optical flatness, and is coated with multiple layers of high refractive index materials. The element must be protected from the environment, in particular to prevent surface damage from humidity. This requires the instrument to be hermetically sealed, purged, or protected by desiccant. For demanding applications, nonhygroscopic materials, such as barium fluoride and zinc selenide, have been used for beamsplitter construction. One other fall-out from the requirement for high optical tolerances, all round, is the impact of temperature. Interferometers are inherently sensitive to changes in ambient temperature, and in acute situations can lose optical alignment, with consequent losses in stability and energy throughput.

With careful attention to the basic design, it is possible to construct a rugged interferometer suitable for use in a factory or production environment. Several manufacturers have focused only in this area and a range of systems are available, including on-line process monitoring applications. Even in these cases, operational issues can arise, mainly because of the need to maintain good optical alignments, and the fact that the instrument still features key moving parts. An alternative design of interferometer, known as a polarizing interferometer, has no moving parts, and at least two commercial designs have been reported, mainly for operation in the NIR region. However, this concept has not been readily received or encompassed by the major FTIR vendors. The down-side to most interferometers, even those designed for alien environments, is the relatively high cost, and the overall size and system complexity. However, for the moment, in the mid-IR spectral region, with the exception of a few multi-wavelength filter instruments, there is no other practical choice of technology available.

### 4.3 System Requirements for Process Infrared Analyzer Systems

There are some very clear guidelines that must be followed in the development of instrumentation for industrial process-related measurements. On the surface, there are compelling reasons to transfer traditional instrumentation technology from the laboratory out to the manufacturing line. A common assumption is all that is required in the development of a process analyzer is to repackage the laboratory instrument into an industrial-grade enclosure. Many instrument companies have fallen into this trap. While this concept might work initially in the early prototyping phases of an instrument’s development, it seldom works for a final process analyzer product. The bottom line is that there is much more to a process analyzer than simply the repackaging of an existing instrument. It is a matter of measurement philosophy, overall system design philosophy and in fact a complete change in operational concepts. Before addressing the different requirements of process instrumentation, it is necessary to classify the mode of operation and the operating environment of the analyzer. Also it is necessary to revisit the term *process analysis*.

First, it is worthwhile to provide a logical separation between the terms instrument and analyzer. Typically, an instrument provides a measurement which requires interpretation of the data generated, and is usually totally open-ended and flexible in terms of sampling and operation. An analyzer is a total system which includes the sampling, the definition of instrument settings, a defined user interface, and a predefined method of measurement and calculation of results. Generally, when focusing on process instrumentation, one is dealing with analyzers. For the purposes of this article, process analysis will be defined as any analysis that is performed to provide feedback to the manufacturing process, in terms of raw material quality (screening), the progress of a process – whether it is batch or continuous – and final product composition/quality. This can range from dedicated laboratory-based instrumental methods for offline testing to continuous on-line measurements with an environmentally hardened analyzer. The following gives the classes or platforms of process analyzer that can be defined.

#### 4.3.1 Laboratory-based Analyzers

These analyzers are often derived from standard laboratory-instruments. However, once well-defined, the system can be provided as a custom-designed or dedicated analyzer. For a spectrometric analysis (IR, NIR or Raman) the main issues are ease of sample handling (usually without modification of the sample), a simple operator interface and automated calculation and reporting of results. Within the laboratory, a single analyzer might be multifunctional, providing analyses for a range of samples. In this case, the analytical methods tend to be “recipe-based” and are usually prepared by a separate research and development group, and are typically stored on a disk file. The procedures usually require very little operator input, although a documented audit trail is usually available in the event that a measurement is questioned. Once a method becomes *standardized* there is an opportunity...
to develop a standard analyzer just for that measurement. This is particularly beneficial in the case of regulated analytical procedures. Obviously, there are minimum instrument performance requirements for a given analysis, although the most common sources of variability and nonreproducibility in spectrometric measurements originate from the method used for sample handling.

- Most important design issues: simple sampling, ease-of-operation, recipe-based analyses (stored methods), automated data evaluation and reporting of results.
- Typical examples: a dedicated laboratory instrument equipped with a permanent sample handling system (sampling station) and with quantitative and/or qualitative analysis software; a flexible laboratory analyzer that can be “programmed” for dedicated analyses; a dedicated analyzer for specific analyses, such as the measurement of unsaturation in polymers, prepolymer and monomers, hydrocarbon characterization (PONA, PIANO, etc.), or hydroxyl value. Other examples outside the traditional chemical industry include semiconductor analyzers focused on established methods used in the semiconductor industry.

4.3.2 Plant-based Off-line Analyzers for Near-line or At-line Measurements

While plant-based off-line analyzers might share a common heritage with laboratory-based instruments, their design requirements are typically more rigorous and demanding. Laboratory-based instruments are normally packaged in a molded plastic or sheet metal housing, with standard power and data cable connections. When working in a plant environment, it is necessary to protect the instrument from the operating environment, and to ensure that the instrument conforms to factory and worker safety requirements. These impact the way that an instrument/analyzer is packaged, and in the nature of the electrical connections used for power and data transmission.

Another critical issue is that a process analyzer is normally required to function 24 h a day, and should work reliably for all work shifts. It is very undesirable for an analyzer to fail unexpectedly during a late night or an early morning shift. This requires a high degree of reliability, which is a design issue – normally achieved by minimizing critical moving parts, and by using components with long mean time between failure (MTBF). This latter point is one of the main arguments away from FTIR, and in favor of newer methods of measurement that by-pass the need for critical moving parts.

Simplicity of sampling and analyzer operation was stressed for the laboratory analyzer. This requirement is even more essential within a true plant environment. Sampling must be highly reproducible, and should require only a minimum of operator skill. One must not second-guess an operator when designing the sample–analyzer interface. The same applies when implementing an operator user interface on the analyzer. Ideally, the analyzer should feature push-button controls, with a minimum number of buttons. If a keyboard input is required, the number of keystrokes for any operation should be kept to a minimum. All visual displays must be kept as simple as possible, they must be unambiguous, and any cautions, warnings or error messages must be clearly displayed. Where practical, universally accepted symbols must be used, and when important messages are presented in written form, ideally they must be presented in the local native language (especially for instruments used in European Community controlled countries).

In terms of packaging, attention must be paid to several issues. Most modern analyzers feature a personal computer (PC) (usually an IBM compatible platform) for data acquisition, control, data analysis, presentation/display of results and communications. There are two approaches that can be adopted when using such a system: either the computer is integrated into the analyzer package, including the visual display and keyboard/control panel (an abbreviated keyboard or a preprogrammed equivalent), or a separate industrial-grade computer is used. An entire industry has been established around industrial-grade computers, from high-performance single-board computers configured for use on a passive back plane for integrated analyzer designs, to rack-mounted PCs and/or environmentally hardened PCs for systems requiring separate computers. This includes keyboards and input devices (mouse, touch-pad or trackball), and displays, which may feature integrated touch-sensitive screens. Touch-screen technologies have advanced to a point where they are robust and quite suitable for use in “non-ideal” factory or plant environments.

The main analyzer ideally should be mounted within an environmental enclosure, which is sealed to provide protection from water and dust. It is not uncommon that an analyzer must be required to withstand direct spray from a high-pressure water hose or a steam line. Typical ambient operating specifications require the capability to operate in a wide range of humidity (from zero to 100%) and over a wide temperature range, at minimum from around 0 °C to 40 °C, often wider. If there is the risk of exposure to flammable vapors, either incidentally or continuously, then the analyzer is normally required to conform to fire safety codes. These normally require that the analyzer is purged with positive pressure, and that it is equipped with a power interlock linked to the presence of positive pressure (and flow for Cenelec code compliance). A standard format for such analyzer requirements is
if a laser in a FTIR instrument is to be replaced, there require sophisticated alignment procedures. For example,ponents, the replacement must be simple, and must not an unexpected failure. For this reason, for such key comp-
ulated maintenance period. This reduces the likelihood of limited lifetime is usually replaced during such a sched-
plant shutdown. Any component that is known to have a
planned and is usually carried out during a scheduled
safety related issues. Generally, maintenance must be
are similar to the requirements described above
range of frequencies.

- Most important design issues: minimum sampling,
push-button operation, recipe-based analyses (stored
methods), automated data evaluation and reporting
of results, high reliability, reproducibility, and sta-
ility, and packaging providing ample environmental
protection to the analyzer and conformance with local and industry-standardized safety and fire hazard
operating codes.

- Typical examples: an analyzer located at a loading
dock for screening delivery of raw materials and/or
shipment of final products; an analyzer located in a
warehouse for raw material screening and inventory
control; an analyzer located in an analyzer room or
adjacent to a batch reactor for monitoring a process or
processes from collected samples; a mobile analyzer
used for process optimization or for trouble shooting
of batch or continuous processes.

4.3.3 Plant-based On-line Analyzers

The overall requirements of an on-line analyzer in gen-
eral are similar to the requirements described above for
an off-line process analyzer. The main difference is that the analyzer normally operates 24 h a day, unat-
tended, when implemented on continuous processes. This
places an even higher dependence on high reliability and
safety related issues. Generally, maintenance must be
planned and is usually carried out during a scheduled
plant shutdown. Any component that is known to have a
limited lifetime is usually replaced during such a sched-
uled maintenance period. This reduces the likelihood of
an unexpected failure. For this reason, for such key com-
ponents, the replacement must be simple, and must not
require sophisticated alignment procedures. For example,
if a laser in a FTIR instrument is to be replaced, there
must be no need for tedious alignment, often associated
with laser replacement in laboratory-based instruments.
It should be possible for an average electrical technician
or maintenance engineer to replace this component.

Most on-line analyzers are installed as permanent
fixtures. The only exception is for process monitoring
studies, where a spectrometric analyzer is used to charac-
terize and/or optimize a process. For these applications,
a semipermanent system, capable of being moved from
process to process, with a degree of re-configuring, is
installed. Note that overall, such a system must meet
all of the normal requirements of a process analyzer,
except it will feature greater variability in sampling and
configuration options than a permanent system.

Bearing the needs of a permanent system in mind,
the environmental issues of temperature and vibration
become more critical, and the requirement for confor-
ance to safety standards may be enforced by the needs
for system certification. The latter requires an assess-
ment of the working environment, and the potential for
fire and/or explosion hazard, relative to the presence of
flammable vapors or gases. Note that safety hazard and
local electrical design code compliance, which include
the CE Mark for Europe, Canadian Standards Asso-
iation (CSA) for Canada, and possibly Underwriter’s
Association (UA) for the USA, may be a requirement
for both off-line and on-line analyzers for certain appli-
cations and/or operating environments. Certification may
be performed by recognized organizations such as Factory
Mutual (FM – USA) or TÜV (Germany).

System installation requirements can be more demand-
ring for a permanently located system, as these may require
a sample conditioning system (featuring some degree
of automation, such as automatic cleaning and outlier
sample collection) and the need to interface to an exist-
ing control system (process computer). The latter may
require that the system provides for some standardized
form of communications protocol, such as Modbus, for
the chemical industry. It should be recognized that certain
specialized industries have their own protocols, such as
the semiconductor industry, which uses protocols known
as SECS and SEC-II. Also, the Universal Fieldbus as a
method/protocol for process analyzers is gaining ground,
although fractionated by more than one manifestation of the
standard.

With some idealistic thinking, for applications involving
the use of optical fiber-based sample interfacing, it has
been proposed that the main analyzer can be placed inside
the main control room, possibly within a standard 19-inch
electronics rack. Although this is certainly not out of
the question, and several analyzers have been effectively
designed with this format, not all end-users favor this
style of installation. The more common approach is to
locate the analyzer within an analyzer house. With such
a configuration, it is not unusual to locate the sample cell and sample conditioning system within a hazardous location, and to install the instrument in a general purpose, or a safe area, with the optical fibers used for the analyzer–sample cell/sampling system interface. \(^{21}\) (Note that the use of optical fibers in the mid-IR region covered by most FTIR instruments is very limited. Currently, common choices are zirconyl fluoride glasses, which provide a spectral window down to around 2000 cm\(^{-1}\) (5.0 µm) and the chalcogenide glasses, which may be used from around 3300 cm\(^{-1}\) (~3 µm) to 800 cm\(^{-1}\) (12.5 µm). However, in the case of chalcogenides, the length of fiber that can be used is typically limited to a few meters (sometimes less than 2 m, dependent on quality) because of transmission losses, usually linked to impurities. Note for some applications, a practical alternative to optical fibers is light-pipe technology (optical conduit), where the sampling interface is interconnected to the instrument via a series of light pipes with flexible connections. While this approach works well for certain applications, it is also distance limited, both in terms of bulkiness and light losses.) For such installations, there is less requirement for the analyzer to conform to safety standards, and the rack-mounted format is quite suitable, assuming that a rack assembly is available to house the analyzer. Without a rack in place, a rack-mount style system may still be mounted within an analyzer house, either on a shelf or on rails.

- Most important design issues: sampling system (possibly automated), minimal or no user interface, recipe-based analyses (stored methods), automated data evaluation and reporting of results, standardized communications (such as Modbus), high reliability, reproducibility, and stability, and packaging providing ample environmental protection to the analyzer and conformance with safety and fire hazard operating codes. An exception to this requirement is for analyzers that can be located within a safe environment, such as in a control room, in such cases, a 19-inch rack-mount enclosure format may be preferred.

- Typical examples: a permanently mounted analyzer for on-line reaction or product-line monitoring with an in-line or a side stream sample probe; a fully integrated analyzer for process control with sampling system and communications for a process feedback loop, such as a refinery stream analyzer for fuel component production and blending; an analyzer for monitoring polymer extrusion with the sampling probe integrated into the extruder head; a system configured for gas analysis for production gases, effluent or process gases, and/or combustion gases.

The functional purpose of many on-line process analyzers is often the same as for off-line applications. Consequently, many of the design requirements are similar. A very practical design concept is to use common instrument measurement technology throughout, providing all three analyzer platforms defined above. This should result in a laboratory-based system, with adequate flexibility for methods development, and the ability to handle both off-line and on-line plant applications as required. One of the most important consequences of the use of common technology is that it provides the opportunity to use instrument standardization methods, and to achieve calibration transferability between analyzers, whether installed in a laboratory, or at or on a process line. However, having stated this, the final process analyzer is typically more expensive than the standard laboratory analyzer, and is usually not an attractive or desirable option for calibration. This can make the final analyzer prohibitively expensive for certain applications – FTIR is a case in point. Therefore, there is a trend in certain areas to consider the use of simpler technology, including a filter-based instrument for the final installation, where all of the initial work is performed on the more sophisticated instrument, and then the calibrations are moved over to the simpler instrument with a suitable calibration transfer function.

If the FTIR process analyzer is evaluated in terms of the issues outlined for the different analyzer platforms, it is possible to indicate potential areas of weakness or areas that may need further attention. Traditionally, the main issues are safety, reliability and serviceability, vibration, temperature, optics, sources and detectors, sample interfacing and sampling, and calibration.

### 4.3.3.1 Safety

Within a FTIR instrument there are several potential safety hazards. The source is one – providing local temperatures at the source in the range of 1100 K to 1500 K. The other is the laser and its power supply, which is a potential spark generator. Both are potential fire hazards. Methods for thermally isolating – and possibly sealing – the source are important, especially if an analyzer is to meet fire safety codes. For the laser, there are special power dissipation requirements to ensure adequate discharge of any built-up charge within the capacitance circuitry of the laser power supply.

### 4.3.3.2 Reliability and Serviceability

In the past, FTIR instruments have been considered to be complex and unreliable devices (from a process engineer's view). Attention must be paid to system environmental stability, the reliability of key components, such as optics (non-hygroscopic preferred), electronics, lasers and sources. If a component has to be replaced, then a nonspecialist
technician should be able to perform the task. Complex optical alignments must be avoided at all costs.

4.3.3.3 Vibration Vibration can be a killer for any form of instrumentation. FTIR is a special case because the fundamental measurement is vibration sensitive. Care must be taken in the design of the mirror drive system and the associated optics to ensure that the spectrometer is immune to vibration. A common source of problems can often be traced to mirror mounts that may vibrate if not designed correctly. With a FTIR instrument it is necessary to ensure that the components that are supposed to move do continue to move, and to prevent those that are not supposed to move from moving. Constant vibration can work components loose, and so the extensive use of a screw bonding (adhesive) medium, is strongly recommended, even for noncritical components.

4.3.3.4 Temperature In any opto-mechanical system, temperature changes can result in dimensional changes, which inevitably cause problems if not addressed, especially with FTIR instruments. Temperature compensation is usually required, and careful attention to the materials used for critical components, with regard to expansion coefficients, is essential. This even includes screws and bonding materials. If correctly designed, the optical system should function over the temperature range defined (typically 0°C to 40°C). At issue is the rate of temperature swings – most systems can tolerate gradual swings if designed correctly. Rapid thermal transients can be more problematic, where a rapid rise in temperature may result in thermal shock of a critical optical component. At issue also, relative to thermal design, is the impact on local electronics. Unless designed or specified for high temperature operation, many electronic components can fail or become unreliable at elevated temperatures.

4.3.3.5 Optics Two key issues relative to optics have already been addressed – that is the requirement for non-hygroscopic optics, especially for exposed transmissive optical surfaces (lenses and windows) and the need to pay attention to mirror mounts relative to vibration and/or thermal effects. In terms of nonhygroscopic optics, zinc selenide is a useful material, especially when anti-reflection coated; if a good coating is used, the transmission can be as good as or better than potassium bromide. If potassium bromide has to be used for its lower transmission range (down to 400 cm⁻¹) then a protective coating can be considered. Many forms of coating have been offered, but most have the potential to fail at very high levels of humidity (near 100% or condensing). A process instrument may feature protective windows to help maintain purge and/or for safety reasons. If used, care must be exercised in ensuring that back reflections into the interferometer are avoided, because these will cause photometric errors.

4.3.3.6 Sources and Detectors This critical area is one of the most demanding and also one which is open to new technology. Most sources have a finite lifetime, and hence are considered as replaceable items, also they are a source of considerable heat, which must be successfully dissipated (see comments above regarding temperature). Detectors are of similar concern. For many applications, where the interferometer can scan at relatively low speeds, without any undesirable vibrational/mechanical problems, the traditional lithium tantalate or DTGS detectors may be used. These pyroelectric devices operate nominally at room temperature (do not require cooling to function) and are linear over three or four decades.

For some applications, as a function of interferometer stability, sample interfacing, speed of spectrum acquisition, or sensitivity, it is necessary to resort to a higher performance detector, such as a MCT detector. This detector is capable of high-speed acquisition and has a very high sensitivity (up to two to three orders greater than DTGS). The main issues here are practical, as discussed earlier (section 3.1.3), relative to the need for cooling down to liquid nitrogen temperatures (77 K), and the fact that the detector exhibits nonlinearity with absorbances greater than one (unless electronically corrected).

Note also, that although a DTGS detector normally does not require cooling, it will stop functioning as a detector, because of depolarization, at temperatures above 40°C. From a design point of view, it is important to note that internal instrument temperatures can be up to 10 degrees higher than the external ambient temperature. Therefore, there is often the need to temperature control or thermally stabilize a DTGS detector in a process analyzer. In this case, a simple, one-stage Peltier (thermo-electric) cooling device will suffice.

4.3.3.7 Transfer Optics Getting the IR beam to the sample, especially within a classified (safety) environment, and ensuring optimum interaction with the beam, can be a major challenge. Gas samples, in particular non-flammable samples, are not necessarily too difficult to deal with. One of the main issues here is paying attention to the corrosivity of the gases, relative to the windows and any internal optics (as with a folded pathlength cell). Liquids offer a completely different set of challenges. Where possible, users prefer to minimize the use of valves, by-pass streams and auxiliary pumps, especially over long distances from the stream to the analyzer. Therefore, there is a need to sample the stream either directly or as close as possible to the stream. As a result there is often the need for transfer optics from the sample cell to the spectrometer. There are a couple of quite elaborate schemes for
“piping” the light from the spectrometer to the sample and back. While these do work, they are typically cumbersome, and they can be awkward to implement, and maintaining alignment and optical throughput can be a problem.

The use of fiber optics has already been mentioned, and it is worthwhile to consider their use in context. In the mid-IR they may be used for certain applications, but currently, their use is limited when used within the important fingerprint region. The fiber materials of choice have been zirconyl fluoride and chalcogenide glasses. The latter is transparent throughout the fingerprint region down to around 800 cm\(^{-1}\), but with a sacrifice of energy throughput due to high attenuation losses, caused primarily by impurities in the glass. The result is a limitation on fiber length, and on the choice of suitable detectors – MCT is normally required to handle the low light levels. Work is continuing on mid-IR fiber materials, and with the recent introduction of silver halide fibers and capillary light fiber guides, which provide a better transmission range than chalcogenide glasses, and also much lower attenuation losses, the interest in the use of fiber interfacing is expected to continue. Note that the silver halides are only suitable for the mid-IR range because at shorter wavelengths, especially with visible or UV wavelengths, darkening of the silver halide matrix occurs.

The limitation on the use of fibers does not apply in the NIR, where common silica-based optical fibers work well. Note that it is essential to use low-OH fibers to reduce absorption losses due to OH absorptions over the length of the fiber. The use of fiber optics for NIR applications is now well established, and for many applications this is a favored method for interfacing the spectrometer to the process. For certain applications, fiber distances of up to 1 km have been implemented. For most gas or liquid phase applications, a single filament fiber is adequate. However, for applications that involve reflectance measurements, especially with diffusely reflected radiation, fiber bundles are more beneficial in terms of light collection over a large solid angle. The trade between single filament versus multiple fiber bundles is light gathering efficiency versus cost of implementation, as well as coupling efficiency with the spectrometer. Fiber bundles can be very expensive, in terms of cost per meter, and so their use tends to be limited to applications with a short distance between the sampling point and the spectrometer.

While the use of fibers might seem to be a logical choice in terms of applications within a hazardous environment (flammable or toxic vapors), they may not always be the final or preferred choice. Light transmission and attenuation are not the only factors for consideration. Temperature and mechanical shock and/or vibration are other important parameters. The transmission efficiency of a fiber is strongly affected by temperature changes and vibration, and this can lead to poor spectrometry, and unstable baselines. Care must be taken in the way that fibers are mounted and packaged, especially when used externally.\(^{21}\)

4.3.3.8 Diagnostics There is more than one type of fault that can develop with a process analyzer. A component failure is often relatively easy to diagnose, and so on-line fault-finding can be straightforward. The more insidious problems occur with the analysis itself, or when a component ages, but does not fail, or when a sampling device gives problems (such as corroded or coated windows of a cell). Many of these problems are application dependent, but where possible the failure should be anticipated, and preventative measures put in place to reduce the impact, or at a minimum provide adequate warning of failure. Note that the fact that a FTIR instrument is a full-spectrum device, providing a significant amount of over-sampling, is very beneficial for both application diagnostics and also calibration purposes, when compared to filter-based analyzers.

4.3.3.9 Calibration Most process analyzers are designed to monitor concentration and/or composition of a product or intermediate. In such cases it is necessary to calibrate the analyzer from a set of prepared concentration standards or from well-characterized reference materials. The simple approach should always be adopted first, and for relatively “simple” systems the standard approach is to use the Beer–Lambert law relationship, where the measured absorption is directly proportional to the concentration of the analyte.\(^{22}\) Traditionally, each analyzer is calibrated locally against the standards. In more complex chemical systems, it is necessary to adopt either a matrix approach to the calibration (still relying on the Beer–Lambert law) using simple regression techniques, or to model the concentration and/or composition with one or more multivariate methods, an approach known as chemometrics.\(^{23–25}\)

4.3.3.10 Standardization There is the need to model and compensate for the instrument response function, which will vary from analyzer to analyzer. The ability to address these issues will be essential if calibration transfer is to be achieved across all instrument platforms.\(^{26}\) Also, there is often a need to be able to perform local standardization and analysis calibration while the instrument is on-line without taking the system off-line or out-of-service. Ideally, on-board calibration/standardization can be integrated into the sample conditioning system. Most commercial NIR analyzers feature some form of standardization and calibration transfer. In fact such schemes are essential to minimize the need to perform frequent calibration – an act that could be cost and time prohibitive in a production
Similarly, many of the modern FTIR (and Fourier transform NIR) systems also include some form of instrument standardization, often based on an internal calibrant, such as a “standardized” polymer film. This is becoming an important feature for regulatory controlled analyses, where a proper audit trail has to be established, including instrument calibration.

Overall, most of these requirements are straightforward to implement, but they do require attention at the design level. One other area of importance which is not particularly FTIR specific (although it may be in some areas) is the user interface and the need to provide industry standard data communications. One option here may be to use a standard software package from a company such as Intellution or Wonderware – both recognized products for process interfacing and control. For prototype development, and even for the front-end interface in a stand-alone mode of operation, software products, such as Microsoft’s Visual Basic and National Instruments’ LabView, are also very flexible tools for instrumentation software. This latter company also provides important computer-based electronics that meet most of the computer interfacing and system control and communications needs.

As previously noted, many of the needs specified are driven directly by the known needs of the traditional process analyzers. When it comes to the high-technology fabrication industries (semiconductors, optics, vacuum deposition, composites, etc.), consumer-associated industries, such as the automotive after market, and environmental, safety and hygiene applications (United States Environmental Protection Agency, United States Occupational Safety and Health Administration, etc.), the needs can be different. Instrument reliability and performance are important in all aspects, and operator safety requirements are much the same throughout, although the actual standards may be different, dependent on the regulating agency. For some of these specialized areas of application, the need to follow well-defined operating procedures and operating protocols is essential, and full documentation of audit trails are often a requirement. In certain cases, ISO 9000 certification may be a prerequisite.

4.4 Sample Handling in a Production Environment

Throughout this article, many references have been made regarding the sample, how it is handled and presented to the IR instrument. Sample handling in the IR has become a major subject for discussion over the past 20 years, and is covered well in several standard texts.\(^\text{27–31}\) IR spectroscopy, when compared to other analytical techniques, tends to be unique relative to the large number of sample handling technologies that are available. Selecting the correct or appropriate technique is extremely important relative to the overall success of a process-related application. This applies equally to both off-line and on-line styles of analyzers. The only difference for on-line applications is that the sample handling method must be sufficiently robust to maintain optical performance throughout operation. Attention must be paid to sample corrosion, pressure and temperature effects, and this often requires the use of specialized and even exotic materials for both the optical elements and the cell fabrication materials. Optical materials such as sapphire, cubic zirconia, and even diamond may be used for demanding applications, as long as the optic transmission range matches the needs of the measurement. Likewise, materials such as nickel, Monel\(^\text{®}\) and Hastelloy\(^\text{®}\) may need to be used for cell construction.

Probably the most important factor in selecting the appropriate sample handling technique is to try to work with the sample material as it exists, without any form of chemical or physical modification. For gases and certain liquids, simple transmission cells, often with a flow-through configuration, will work for both NIR and mid-IR measurements. Samples that are strong absorbers of IR radiation will cause problems for mid-IR measurements. In the laboratory, there is a possibility to reduce the sample pathlength for such samples, but in a flow through configuration this becomes impractical. This problem does not usually apply in the NIR, where sample pathlengths are typically one or two orders of magnitude larger (typically between 1 mm and 100 mm) than in the mid-IR.

A common solution to the pathlength problem in the mid-IR is to use one of the many styles of ATR (attenuated total reflectance) sampling devices. These are available in a number of different configurations, providing both methods for manual sample loading (horizontally mounted sampling points and dip probes) and automatic flow through methods. A range of materials, including diamond, are now available for these optical devices. The technique utilizes a surface measurement (to a depth of 1 or 2 \(\mu\)m), and so careful attention must be paid to surface contamination and fouling, especially for on-line, flow-through applications. Fouling of the surface not only causes interferences and/or potential energy losses, but it can also change the photometry of the experiment by modifying the refractive index of the surface. In such cases, it is important to try to implement algorithms for detecting material build-up on the surface. Cleaning schemes can be invoked, and by definition, this implies the incorporation of some form of sampling system. For some applications, a simple flushing or back flushing with a solvent may suffice. If the material adheres strongly to the surface, it may be necessary to implement some form of mechanical cleaning of the surface. One practical alternative approach, that is
available on a commercial FTIR process analyzer, is to use an ultrasonic cleaning system.

It is a general perception that sample handling is easier in the NIR region. To some extent this is true, because longer pathlengths may be used for liquid sample handling, and direct reflectance methods, such as diffuse reflection, may be used for convenient sampling of solids. While diffuse reflectance can be used in the mid-IR, optically related artifacts in the measurement tend to limit its use to purely laboratory applications. Even in off-line applications, where an operator is involved in the sample handling, it is important to keep the sample presentation as simple and as reproducible as possible.

4.5 Factors Influencing Acceptance of Spectrometer-based Analyzers

4.5.1 Low Maintenance and Turnkey Systems

Given the conservative nature of the average process engineer, there is a need to supply the system as a turnkey product. It is expected that the product will be operational “out-of-the-box”, and will require little technical support at the time of installation. Once installed, it is expected that the system will operate with minimum operator attention. Also, any maintenance requirements should fit into a scheduled maintenance program. Any items that are likely to fail within a given time-frame must be identified, and recommendations for scheduled replacement must be provided. With a FTIR system, components such as sources and lasers are often the most likely to fail, and a knowledge of the MTBF for these is important.

Note that on-board dedicated processors are appropriate; however, integrated hard disk drives are not recommended, and if on-board storage is required, it is recommended that alternative solid-state storage, such as flash random access memory (RAM) or battery-backed RAM is used. Critical moving parts in analyzers are always subject to critical assessment. One factor to bear in mind is that early false starts with FTIR have left a slight stigma against the technology. Much of this is linked to mechanical and environmental (vibration and temperature) issues. It is important to re-enforce design features and attributes that address past concerns of system stability and reliability.

Finally, relative to maintenance issues, the requirement for high cost replacement parts must be kept to a minimum, unless the frequency of replacement is once every 3 to 4 years. For FTIR analyzers, this may not be a problem, as long as components are simple to replace. If an entire sub-assembly needs replacement this could represent a maintenance issue. Key replacement items that need attention, in terms of ease of replacement are sources and lasers. Laser re-alignment after replacement is also an important issue – it must be easy to perform, and should not require a person to perform major optical adjustments. If interferometer alignment is required, then this should be automated via a mechanized auto-align procedure.

4.5.2 Multipoint Monitoring Considerations

One of the benefits of certain types of optical instrumentation, that can be interfaced via fiber optics, is that there is the possibility to use an optical multiplexer, and monitor several points with a single instrument. This approach has been used successfully with NIR instrumentation, where typically up to 8 points can be handled (note that one vendor provides a multiplexer that handles up to 20 inputs). With sequential access on a multiplexer, the elapsed time is still the measurement time multiplied by the number of points – only the overhead with the sample lines does not apply. Having stated this benefit, the use of fiber optics with mid-IR Fourier transform instruments is limited, and relatively exotic fiber materials must be used. One or two commercial multiplexers have been offered for mid-IR fiber systems, but their use has not been widespread.

The opportunity to reduce the cost per analysis point can be very important for certain applications. For the most part, FTIR, when applied to process applications, is often best implemented with a direct optical coupling with the sample. In this case, there is the preferred option to use sample stream multiplexing with a manifold system. For gas-based systems this is very straightforward, and does not impose a high cost overhead. Liquid systems may be more complex, dependent on the nature of the stream involved, and material reactivity, miscibility or viscosity are important issues to address.

4.5.3 General Cost Considerations

If a spectrometer is replacing a service intensive, or possibly more than one service intensive technique, then it is obviously a positive situation. However, if it is necessary to maintain complex chemometric methods, as with some of the NIR applications, and also bear the potential burden of problems associated with calibration transfer, then it can be a large negative factor. Typically, such costs of ownership are estimated over 5- or 10-year time-frames. Note that FTIR systems operating in the mid-IR, or even in the first overtone (Fourier transform NIR) are typically much easier to calibrate, and provide a more robust calibration than traditional NIR instruments. As a result, cost benefits can be demonstrated with FTIR analyzers, which are not necessarily achievable with comparable NIR analyzers.

Calibration is an issue with all spectrometric analyzers. Although the cost of single channel (or multichannel)
photometers is low, they often require frequent calibration, which raises the cost of maintenance, and likewise the cost of ownership. The highest cost of ownership can be experienced with NIR instruments, where chemometric calibrations may need to be maintained on a regular basis. This can add a tremendously high cost of ownership (a qualified chemometrician might be required). Surprisingly, this has not been a major issue in the refining industry, possibly for two reasons: the NIR replaces several traditional analyzers, which in total have a much higher cost of ownership; and in many cases, the burden of maintenance is placed on the instrument vendor (in the form of a service contract).

5 APPLICATIONS OF PROCESS INFRARED SPECTROSCOPY

Having placed IR spectroscopy in perspective relative to fulfilling the needs of the process analysis, it is worthwhile to discuss the technique's strengths relative to specific applications. Also, it is necessary to indicate areas of greatest potential in terms of the physical measurements, and chemical species and materials most amenable to IR analysis. IR provides important information that relates to the molecular structure, of both organic and inorganic materials. Classes of compound that have strong IR signatures, and are important to petrochemical and chemical processing, include aromatic compounds, olefins and unsaturated compounds and branched chain compounds. Beyond these common hydrocarbon classes are virtually all classes of chemical compounds, with most functional groups providing characteristic absorptions throughout the classical mid-IR spectral region. Similarly, many parallel applications exist for inorganic compounds, which typically also provide very characteristic and often intense signatures.

A detailed discussion of potential and actual applications, both industrial and otherwise, is too long to include here. A relatively complete set of lists, that include implemented and potential process, process-related or QC applications, are provided in Tables 2 to 5.

6 PROCESS ANALYSIS: A REVIEW

There are many industrial segments where process spectrometers may be used, ranging from their use in traditional chemicals and petrochemicals manufacturing to fine chemicals and specialized manufacturing, which include pharmaceutical and consumer-oriented products (such as packaged goods and food products). In recent years NIR has become accepted in many of these markets as both a near-line/at-line tool, and as an on-line continuous monitoring technique. There are many areas not covered by NIR, such as gas-phase monitoring.

For these, mid-IR spectroscopy, used in the form of traditional analyzers, or as FTIR instrumentation, has become a method of choice.

Gas phase applications for dedicated process-related measurements can go beyond product manufacture, and can include industrial health and safety, hazard monitoring, and, as appropriate, the needs of various government agencies, including those that focus on the environment (United States Environmental Protection Agency), energy (Department of Energy) and defense (Department of Defense). In the case of many of these agency requirements, monitoring devices are not required by the agency directly, but are used as tools of compliance for industry.

The petrochemical and chemical industries are extremely diverse, and offer many opportunities for process IR.

spectral measurements. Overall, they may be considered as segments of the hydrocarbon processing industry because natural gas and crude oil are considered to be the principal raw materials for a major part of these industries. Products manufactured by the petrochemical and chemical industries range from commodity materials (basic chemicals and raw materials) to fully formulated or compounded end-use products. Value-added products, which are manufactured towards the back end of the product chain, often require an advanced spectral analyzer, such as a process FTIR, whereas commodity chemicals may be adequately served with a traditional analyzer, such as an IR photometer.

In general, IR analyzers are viewed as cost-savers, providing information rapidly, often capable of providing it in “real-time”, and with a minimal amount of operator intervention. IR spectral-based analyzers are still gaining attention in the process analysis world for measurements on almost all types of material.

### 6.1 Process Spectroscopy – a Reality Check

It has been assumed for some time that manufacturing companies want to make plants more efficient and wish to maximize profitability during production. In essence, this is true, but it is not always an automatic assumption that a company will actually implement changes, or install expensive equipment to make manufacturing more efficient. With a cost versus benefit analysis, a company might determine that the savings are too small to justify investment in technology to improve production. This in particular may be the case with an older plant, where a major overhaul may be required to make the changes cost-effective. Alternatively, adding new technology might be just a small part of an overall modernization scheme – it depends on the industry, and it depends on the company. Note also that the requirements for return on investment and/or pay-back of plant instrumentation vary significantly from industry-to-industry: some industries require payback within 6 months, for others, 4 or 5 years may be adequate.

The premise for the use of PAI is that the more information that is known about a process and/or a product, the better the opportunity to control the process and to reduce waste. Also, with the move towards improved quality, and the need to define procedures (ISO 9000, installation qualification/operational qualification/performance qualification (IQ/OQ/PQ) issues, good laboratory practice/good manufacturing practice (GLP/GMP), audit trails, etc.) opens the door for the use of improved analytical methodology. Another important factor, in the early 1990s was the initial reaction to the various amendments to the Clean Air Act. The result of these different influences was to create an over-exuberant atmosphere relative to the actual opportunities for process analytical instrumentation.

Bearing the above issues in mind, the following factors must be considered relative to the use of advanced process IR instruments, with special focus on advanced analyzers:

- Process photometers are well established, and are standard choices for certain, well defined applications. More advanced analyzers should only be considered if the application goes beyond the capabilities of the simple filter instrument.
- The use of NIR on-line process analyzers has become widespread for many areas of chemical and product analysis. At times, the use of these instruments may be constrained by the limited information content of the NIR spectrum, or by the overhead cost of maintaining a NIR calibration. The ability to extend a FTIR instrument to cover the NIR range has broadened the acceptance of both NIR and FTIR.
• Process FTIR has been implemented since the mid-1980s, but its use has been limited to mainly large chemical companies, and to specialty manufacturing industries (such as gases, semiconductors, pharmaceuticals).

• In traditional petrochemical and chemical production (primaries and intermediates), GC tends to be the PAI technique of choice. IR photometers are used, but mainly for environmental applications. IR spectrometers, including those based on FTIR methods are gaining acceptance for certain applications, such as fuel products (gasoline, diesel, etc.).

• Beyond the intermediates, and into the value-added business areas of the petrochemical and chemical industries, techniques such as NIR and IR are used extensively, but usually in an off-line role, or at the pilot plant level for reaction monitoring on-line.

• Technology champions within an organization have proved to be important for the successful implementation of advanced spectrometer systems.

• New emerging technologies, such as detector arrays and diode laser-based systems, are starting to be used for specialized applications. Scaling-down or miniaturization could lead to more cost-effective analyzers. If this occurs, it is expected to result in a paradigm shift relative to how process IR analyzers are perceived and implemented.

As a general commentary, a focus on a specific application has fostered a significant number of IR (both mid-IR and NIR) instrument developments based on either new or existing technologies. While such devices on the surface are limited to the application, with some modification they can be applied more generally. Many of the developments are either sponsored by governments (for military, aerospace, energy, and environmental applications) or are spawned from projects undertaken by engineering consulting firms for major manufacturing companies for a specific application. Such products come to market, often indirectly, as the result of partnerships between technology companies, instrument vendors, engineering companies and/or end-users.

One example is the refrigerant analyzer developed for the automotive industry for the determination of Freon®/halocarbon type in vehicle air conditioning systems. Specific filters define the analytes, and the packaging is small and inexpensive; such a system can be easily adapted for process applications. Examples such as this are applications driven, and the products are often developed quite independently of the traditional process analyzer business.

Full spectrum analyzers, such as NIR and FTIR spectrometers, have important attributes that can be turned into distinct advantages for certain applications. These include:

• the ability to handle a broad range of sample types;
• in-line sampling for gases and liquids (liquid ATR probes for FTIR);
• the ability to handle even corrosive materials with suitable hardware and sampling aids;
• the selectivity and specificity of IR (mainly mid-IR), with good spectral response for key structural/functional groups.

7 FUTURE TRENDS AND DIRECTIONS

A large number of traditional instruments are sold into industry for QC applications. For applications such as raw material screening this scenario is working adequately. However, there is a growing interest in the ability to make measurements in many areas of a process, with the idea that better production control can lead to a better control of the process and of the quality of the final product. While PAI have been a partial solution in certain industries, the cost of implementation is often very high, and it is impractical to implement more than a couple of instruments on a production line. Also, there is growing concern about the operating environment, worker safety and environmental controls. The ideal scenario would be to have the power of a full-blown vibrational spectrometric analyzer but with the cost and simplicity of implementation of a simple filter device.

There is a potential paradigm shift, with the understanding that if an analyzer becomes simpler and less expensive to implement then the role of PAI instruments could expand significantly. Furthermore, there is the understanding that “good enough is OK.” This opens the way for spectrometer devices with lower resolution, shorter spectral ranges, and with multiple wavelength selection customized to the analysis. Many such devices have been already contemplated in different arenas, in particular for aerospace, military and defense applications, and in certain medical applications. Many of the technologies outlined in this article can lend themselves to this change in understanding. The use of specialized enabling technologies is expected to provide significant contributions, such as specialized optical coatings, microengineering and micromachining, and alternative light transmission and detection technologies. Most of these come from outside of the traditional instrument industry, and in the future we can expect new generations of instruments and sensor devices that come from sources other than the established instrument vendors. There have been discussions about instrumentation
and, in particular, spectrometers, on a chip. The technology exists, but the market and people are not necessarily ready for this. However, one can expect new generations of small-scale and miniaturized instrumentation in the near future, probably before the year 2005.

Mass Spectrometry in Process Analysis

José A. Olivares
Los Alamos National Laboratory, Los Alamos, USA

1 Introduction

Mass spectrometry is an analytical technique that has been applied to the study and solution of a diverse number of chemical problems. Owing to the complexity of the instrumentation, the majority of the chemical analysis work performed by mass spectrometry occurs in the laboratory, where controlled conditions exist and time for decision-making can be sacrificed for the ultimate in sensitivity and detectability. Nevertheless, mass spectrometry provides a viable tool for the solution of process control and analysis in many industrial settings. In this case, the chemical and physical constraints, and need for prompt action, require that the instrument sample the process on-line and provide real-time feedback control to the operation. In this article we will review some of the aspects of mass spectrometry related to its use in industrial process analysis as it applies to the control of a production process on-line, i.e. the mass spectrometer is physically attached to the process as a sensor that provides real-time feedback. This is in contrast to the more common uses of mass spectrometry at-line or in analytical laboratories, where the process is sampled through grab samples and feedback is not in real-time. The discussion is strictly limited to this topic, even though other problem categories have often been associated with process analysis. Thus, important topics to which mass spectrometry contributes heavily, such as environmental analysis, medical diagnostics, thermal gravimetric analysis, reaction monitoring, and others, are not considered in this article.

The mass spectrometer can provide a versatile, highly specific and sensitive tool for the analysis and control of industrial processes. More common techniques for industrial process control are gas chromatography and infrared spectroscopy. Ion mobility spectrometry and chemical sensors are slowly being introduced. Although mass spectrometry is relatively more complex and expensive to implement than these other techniques, the sensitivity and specificity offered is often unmatched. This article gives a general review of the roots of mass spectrometry as it applies to on-line process control. A short discussion of instrumentation commonly used in the practice of this technique has been added and limited only to the more popular and currently commercially available instruments. These include sector, quadrupole and time-of-flight mass spectrometers. The capabilities and specifications of the different classes of mass spectrometers are discussed and compared. Specific sampling methodology for the operation of these instruments in on-line processes is given. Also included is a discussion of common practices in the reduction of interferences and deconvolution of mass spectra from mixtures. In-depth examples of industrial process and control applications have been selected and are discussed in the areas of biotechnology, technical incineration, petrochemical, and semiconductor production.

2 HISTORY

The history of mass spectrometry as it pertains to industrial process control can be pieced together from a number of classical mass spectrometry texts by Hill, Roboz, and Watson, and reviews by Huber and Cook et al. The first reported use of mass spectrometry to control process streams goes back to the 1940s. In this time period the development of the petrochemical industry required that the precise chemical composition of the feed materials be known. This work was performed offline with grab samples taken to the laboratory for analysis. The emergence of the first commercial mass spectrometers helped to spark the study of cracking patterns of organic compounds for the petroleum industry. Based on Dempster’s single-focusing mass spectrometer (i.e. direction focusing), the Consolidated Engineering Corporation (Pasadena, CA) Model 21-101–103 instruments were responsible for much of the early production of mass spectral data compiled by American Petroleum Institute Research Project 44. These and other commercial instruments could be operated easily by chemists, who focused on the improvement of sample-handling methods. Organic compounds up to 500 Da and with melting points up to 350 °C could be studied using single-focusing mass spectrometers, which provided resolutions of 1000–4000, with mass ranges up to 2000 Da. High-resolution instruments based on double-focusing mass spectrometers (i.e. momentum and velocity focusing) utilizing Nier–Johnson and Mattauch–Herzogg geometries provided an important contribution to the identification of petroleum products. These instruments, with mass resolutions of 5000–100,000, provided the ability to resolve difficult mixtures of compounds in which two or more types of compounds appear at the same nominal mass. Thus, hydrocarbon types in high-boiling-point distillates (160–510 °C) could be identified within minutes. The cycloidal mass spectrometer, introduced in the late 1930s, was first used as a compact residual gas analyzer by Robinson and Hall in 1956. This instrument provides the stability and sensitivity available in magnetic sector instruments in a small package that can be portable and placed easily on an industrial process.

The above-mentioned instruments are termed static spectrometers because the operational parameters of the mass spectrometer remain constant with time, except for the slow change in magnetic and electrical fields required to record a mass spectrum. Similarly, a number of dynamic mass spectrometers have been used to make major contributions to process control and are by far the most popular in use today. Dynamic mass spectrometers are classified as those in which the time dependence of one or more instrument parameters, e.g. electrical field strength, magnetic field strength, or ion movement, is fundamental to the mass analysis. Blauth has published a classical treatise on dynamic mass spectrometry. Some early dynamic mass spectrometers, such as the omegatron, the linear radiofrequency (RF) mass spectrometer, and the farvitron, have enjoyed much success as residual gas mass analyzers for vacuum, rocket, and space exploration, owing to their sensitivity, compactness and lightweight design. Today, the time-of-flight mass spectrometer and the quadrupole mass spectrometer have become the most popular for use in residual gas analysis and process control. The time-of-flight mass spectrometer was first proposed and put into practice in the late 1940s by Stephens. Early on, these instruments achieved partial pressure detection limits of 10⁻¹² mbar for residual gas analysis in vacuum processes, with mass resolutions of 10–60. The quadrupole mass spectrometer was first introduced by Paul in the early 1950s. The first use of quadrupole mass spectrometers as residual gas analyzers was described by Guenther, and since then they have become by far the most popular process analysis mass spectrometer.

3 ON-LINE SAMPLING

3.1 Instrumentation

The process mass spectrometer consists of several key components: the mass analyzer, which actually does the mass separation of the analytical sample; the ion source, required to produce gas-phase ions of the analyte for separation; the detector, used to collect the separated analyte ions and provide a signal that can be measured
and recorded; and the sampling interface, which actually introduces the analytical sample from the process to be measured into the ion source of the mass spectrometer. These components are described here in some detail, with a focus on currently available commercial mass spectrometers used for process monitoring.

3.1.1 Mass Analyzers

The discussion in this article is limited to some of the most common mass analyzers in use today: cycloidal, time-of-flight, and quadrupole mass spectrometers, yet there are many examples in the literature that use other types: magnetic sector, electrostatic sector, quadrupole ion trap, ion mobility, omegatron, farvitron, and linear RF mass spectrometers. In-depth descriptions of these instruments can be found elsewhere in this publication and in other reviews.\(^1\)\(^2\)\(^3\)\(^4\)\(^5\)\(^6\)\(^7\)\(^8\)\(^9\)\(^10\)\(^11\)\(^12\)\(^13\)\(^14\)\(^15\)\(^16\)\(^17\) In principle, any type of mass analyzer can be used for process control. The basic objectives that are most often associated with mass analyzers are mass range, resolution, ion source type, detector type, and sensitivity. Other basic requirements such as size, utility requirements, and system control specifications are more important for site location than actual performance of the instrument, but nevertheless are major contributors to the successful implementation of on-line process analyzers. Both instrument performance and physical specifications make up the basic selection criteria for specific applications.

Table 1 gives some of the basic specifications for common process analyzers available commercially. As can be seen, most residual gas analyzers have been limited in their mass range to 100, 200 or 300 Da. The limitation is due to practicality. Volatility for organic compounds generally decreases with increasing mass. Furthermore, as the volatility decreases, sample introduction into a mass spectrometer becomes more complicated, owing to contamination of the sample inlet, ion source and mass spectrometer vacuum system, resulting in low sensitivity and poor detection. Gas-leak detectors will usually limit the mass range to the leak gas to be detected. Helium is the most useful for this purpose, owing to its low mass, high diffusivity, its inertness and its inflammability, unlike hydrogen. Therefore, gas-leak detectors are usually limited to a mass range of 4 Da. For most residual gas analysis applications involving simple inorganic gases and light hydrocarbons, a 100-Da mass range is sufficient for analysis. In fact the C\(_3\)H\(_7\) peak at mass 43 can be used reliably to estimate the total hydrocarbon partial pressure of a system within a factor of 2.\(^16\) Higher mass ranges may be needed, depending on the application. The trade-off tends to be resolution, sensitivity, and size (physical or power consumption) of the instrument.

The resolution (\(R\)) of the mass analyzer is defined as \(M/\Delta M\), where \(M\) is the mass-to-charge ratio, where the measurement is made, and \(\Delta M\) is the mass width of the ion intensity peak at 10% of the height. For quadrupole instruments \(\Delta M\) is typically unity across the mass range. For time-of-flight instruments, \(R\) should be specified at a particular mass because this quantity will vary with mass. For magnetic sector instruments \(\Delta M\) is typically unity across the mass range. For time-of-flight instruments, \(R\) should be specified at a particular mass because this quantity will vary with mass. For magnetic sector instruments, \(R\) is constant across the mass range because this is fixed by

the geometry of the instrument. Thus, the resolution of different types of instruments should be compared at the masses of interest for each application.

3.1.2 Ion Sources

In order to generate a mass spectrum of a molecule, gas-phase ions of the molecule need to be created. Most process mass analyzers use electron impact ionization. In this technique the sample gas is introduced into a low-pressure region (typically $10^{-4}$ mbar or lower) near the physical entrance to the mass spectrometer. In this region, sample molecules encounter energetic electrons (10–100 eV) that are emitted from a resistively heated filament. When the electrons collide with the sample molecules, ionization can occur by the removal of an electron from the analyte molecule to form a positive ion. This ion is then accelerated and focused onto the mass spectrometer. The ion source configuration is determined by the required sensitivity, the pressure of the analyte stream, reactivity of the analyte and matrix gases, and interferences that can be caused from these reactions and the walls of the chamber. The filament material tends to be thin tungsten wires. Hydrocarbons react with hot tungsten to form W$_2$C on the surface of the filament. This affects the electron emissivity of the filament and requires filament conditioning to form a durable W$_2$C that will not change significantly during the measurement period. Rhenium is another popular filament material that does not form stable carbides, and its oxides are unstable at the required emission temperatures. Furthermore, it does not become brittle at high temperatures and conditioning is not necessary, as it is for tungsten. The filament lifetime tends to be shorter than for tungsten, due to the higher volatility of rhenium. Rhenium is a good material to use when the sample stream contains oxygen or oxygenated compounds. Tungsten reacts with oxygen to form tungsten oxide and carbon monoxide, decreasing the life of the filament and increasing the spectral background relative to rhenium. Yet tungsten is preferred in high-vacuum environments where the volatility of rhenium could be problematic and the long lifetime of tungsten filaments becomes an advantage. Another consideration is the high temperature of $>300^\circ$C achieved by the source, which is known to affect the sensitivity and cracking pattern of the analyte. In this case, thoriated tungsten oxide filaments, lanthanum boride on rhenium filaments, and platinum–iridium filaments provide excellent electron emission characteristics at relatively low temperatures.

Electron impact ionization is a way that the secondary electron emission emitted by the energetic ions impinging on the metal surface is minimized. This is the simplest type of ion detector that could be placed on a mass spectrometer. Closed-type ion sources accomplish this by physically enclosing the ion formation region near the gas inlet with a metal box or cylinder. The closed-type ion source is best used when the process to be monitored is at a pressure significantly higher than the operating pressure of the mass spectrometer, and the gas can be introduced efficiently into the ion source using an inlet capillary or orifice. Open-type ion sources utilize a grid as the enclosure for the ion formation region, and allow the gas in the vacuum chamber to penetrate freely into the ion source. The open-type ion source is utilized when the mass spectrometer is immersed into a low-pressure process chamber that is to be monitored.

Another type of ion source used in commercial process analyzers is the API source. This source, as the name suggests, operates at atmospheric pressure. Ions are generated in a small corona discharge created when current-limited high voltage is applied to a platinum needle in close proximity (5 mm) to a metal plate. Analyte gas at or near atmospheric pressure is introduced directly into the plasma chamber, where it is ionized. The metal plate contains a small orifice, typically 0.5 mm, that samples the plasma gases and ions into the mass spectrometer’s vacuum chamber for analysis. The advantage of this type of source is that it can be used to analyze ambient pressure gas streams or gas streams that can be sampled and swept with an inert gas. Furthermore, this type of source tends to produce mostly molecular ions with very little, if any, fragmentation. The main disadvantages are that it cannot be used to analyze vacuum processes and it requires a differential vacuum pumping system.

3.1.3 Detectors

Process mass analyzers typically will have two types of detectors: the Faraday cup and the electron multiplier. These two detectors often can be found together on systems that require a wide dynamic range in detection. The Faraday cup is a simple small metal electrode; in some instruments it is shaped as a plate but in others it is a small cup that is placed at the end of the analyzer. Ions exiting the analyzer impinge on the metal surface. A high-impedance amplifier or fast electrometer reads the ion current impinging on the metal surface. Often the Faraday plate or cup is shaped or guarded in such a way that the secondary electron emission emitted by the energetic ions impinging on the metal surface is minimized. This is the simplest type of ion detector that could be placed on a mass spectrometer. Depending on the characteristics of the fast-amplifier electrometer system used, ion currents of $10^{-15}$–$10^{-9}$ A can be read easily with this system. Although simple in operation, the Faraday cup has some other drawbacks: susceptibility
to vibrational and electrical noise; and, the lower the ion current, the more complex the electrometer and the larger the time constant for proper readout of the ion current.

Electron multipliers offer an additional 100–1000-fold enhancement in sensitivity and detection for process mass analyzers. In this system a resistively coated tube or set of plates amplifies each ion impact on its surface by emitting $10^3$–$10^6$ electrons. This amplified electron current is then read by a fast-amplifier electrometer. The electron multiplier is typically held at $1000$–$2500$ V negative, with respect to the ion beam, for proper electron emission and gain. Although quite sensitive and very fast in response, this detector has limited linearity and is quite susceptible to burnout by large ion currents and high operating pressures. It is best used in conjunction with a Faraday cup, especially when the analyte composition to be measured can vary widely. Electron multipliers also can be operated in single-ion-counting mode, giving the possibility for the extreme in sensitivity and higher linearity. The instrument’s linearity is an important measurement parameter for process analytical instruments. In mass spectrometers it is typical to have 6–9 orders of magnitude in linearity when using Faraday cup and electron multiplier detectors. Thus, it is possible to measure trace components in the parts-per-billion range, and major components in the percentage range, with these instruments.

### 3.1.4 Sampling System

The term “on-line” analysis is used to indicate the direct coupling of the mass spectrometer to some process that is to be monitored. The sampling system – considered as being the interface between the process to be measured and the mass spectrometer – is a critical component for successful operation. In a low-pressure (usually $<10^{-3}$ mbar) process the ion source to the mass spectrometer is immersed directly in the chamber to be tested and is called the “nude” source. This provides the greatest conductance for the sample to make it to the mass spectrometer, and therefore the greatest sensitivity. If the process to be monitored is at higher pressure, a restriction capillary between the process and the mass spectrometer’s ion source must be provided that will minimize the amount of gas that reaches the ion source and the analyzer. In direct inlet sampling, two types of gas flow are usually encountered, depending on the interface design, molecular flow and viscous flow. In molecular flow the restrictions into the ion source are smaller in diameter than the local mean free path of the gas, and there are few interactions, if any, between the gas molecules. In viscous flow, the mean free path of the sampled gas is small compared to the dimension of the sampling pipe or orifice, and there are ample collisions between the molecules. If molecular flow is achieved along long paths with low conductance, the sampled gas is biased (fractionated) in favor of the lighter gases by a factor of $(MW)^{-1/2}$ due to the velocities achieved, where $MW$ is the molecular weight of the molecule.

Molecular flow sampling has the advantage that the partial pressures of the gases in the sampled reservoir can be represented accurately at the ion source, provided that the reservoir is large. A frit can be used to restrict the flow between the sample reservoir and to provide molecular flow at the source. A restriction capillary, 10–200 µm i.d. and several centimeters in length, is typically used to sample gases near atmospheric pressure into the low-pressure ion source region. This sampling system provides for viscous flow throughout most of the capillary, thus minimizing fractionation effects while providing molecular flow in the immediate region of the ion source. The main disadvantage of viscous flow systems is that the flow is controlled by the viscosity of the gas to be sampled and can vary with the sampled mixture. Furthermore, the partial pressure of a component in the source is not proportional to its mole fraction in the sample, and is not independent of other components present in the mixture. A diagram of such a system is shown in Figure 1, where the restriction capillary along with plumbing, pumps, gauges and valves provide an appropriate sampling system into a process analyzer.

Viscous flow can be achieved for the most of such a system, although true viscous flow is never achieved.

![Figure 1 Vacuum diagram of a process analyzer for use in gas analysis. The optimum pressure range is $5 \times 10^{-3}$ to 1000 mbar. The pressure in the analysis chamber is automatically controlled by a metering valve (A) in front of the restriction capillary (B). Other components include the process mass spectrometer (C), vacuum gauge (D), heated vacuum chamber (E), turbo vacuum pump (F) and rotary vane vacuum pump (G). (Reproduced by permission of Pfeiffer Vacuum from technical note BG800318PE, Copyright Balzers AG.)](image-url)
because at some point near the ion source the flow in such a restriction must change to molecular flow. Nevertheless, the sampled gas is said to be representative of the gas in the process chamber. Careful calibration can result in corrections for biases that give an accurate measurement of the process. Of course, the exception to the need for a restriction capillary, when sampling ambient pressure processes, is when the ion source to the mass spectrometer operates at high pressure, as is the case for the corona discharge ion source of Sensar’s model TOF 2000 (see Table 1). But even in this case there is a 0.5-mm restriction, with differential pumping, between the ion source and the analyzer.

A process analyzer can monitor more than one process, the total number depending on the speed and duration of each process to be monitored. Figure 2 shows a diagram of a process analyzer mass spectrometer connected to a multiple gas stream selector through a heated restriction capillary. Heating and passivation of metal and glass tubes used for sampling a stream are crucial when the gases to be sampled can condense (are adsorbed) and/or react on surfaces. Lining the inside of metal tubes with glass that has been passivated by the method of silanization is a common practice. Notice that the gas in the lines to be sampled is not left stagnant in the stream selector manifold but it is allowed to flow through to waste or back to the process. This ensures continuous flow and rapid response to changes in stream composition. In this manner one process mass analyzer may be multiplexed to many process streams (2–64 are common).

Sampling of gases dissolved in gas and liquid streams can be achieved with the use of a membrane inlet. The basis of this technique is the selective transport of analyte molecules across a semipermeable membrane into the ion source of a mass spectrometer. The technique, termed membrane inlet mass spectrometry (MIMS), has been reviewed extensively. In practice a membrane is used to separate the liquid or gas process stream from the vacuum chamber of the mass spectrometer, as shown in Figure 3. The membrane material should have low permeability for the matrix and high permeability for the analytes of interest. Polypropylene, polytetrafluoroethylene, Teflon™, cellulose, silicone rubber, dimethylvinyl silicone, polyethylene and zeolites are all common membrane materials. Analyte in the process stream diffuses into one side of the membrane and is extracted directly into the gas phase on the vacuum side into the mass spectrometer. Physical (temperature, size exclusion, and diffusion) and chemical interactions (affinity) with the membrane can provide selectivity, preconcentration, and in some cases separation of the analytes. Thus, an overall concentration of the analyte with respect to the matrix is achieved that can be up to a factor of 100. This technique is especially useful where complete vaporization and introduction of the sample into the analyzer would not be reasonable, due to large excess of matrix, time considerations, and sensitivity. Yet, the number of volatile components in the liquid matrix is low and they can be resolved. Although detection limits in the order of parts per quadrillion have been reported for some processes,

![Figure 2](image2.png)  
**Figure 2** Vacuum diagram of a process analyzer for use in the analysis of multiple gas streams. A heated valve system (A) and transfer line (B) provide the ability to multiplex sample streams and calibration gases into the mass spectrometer. Other components shown are as in Figure 1. (Reproduced by permission of Pfeiffer Vacuum from technical note BG800318PE, Copyright Balzers AG.)
some inherent weaknesses are worth mentioning. The membranes can suffer from long response times arising from the diffusion time constant through the membrane, which can contribute to memory effects, and long cycles for the mass transport of the liquid to the membrane.

Finally, it is worth mentioning at this point that mass spectrometers require ambient pressures of $<10^{-4}$ mbar for proper operation. This is mainly due to the fact that at higher pressures, collisions between the analyte ions and background gases affect the ion paths to a greater extent than the mass spectrometer’s electrical or magnetic fields, thus causing loss of sensitivity and resolution. Thus, the mass spectrometer must reside in a vacuum chamber, the complexity of which depends on the application and sample inlet chosen. For example, in semiconductor applications, e.g. vapor deposition, the vapor deposition chamber typically serves as the vacuum system for the mass spectrometer, the ion source is typically nude, and no additional pumping may be required. On the other hand, applications of process mass spectrometry to monitor a high-pressure reactor, e.g. in petrochemical applications, would require a capillary inlet for sampling, and turbomolecular or diffusion pumps along with mechanical forepumps to achieve the required operating pressures. Roboz\(^{1}\) gives an excellent discussion of vacuum systems for mass spectrometry.

### 3.2 Detection Limits and Sensitivity

Two measurement parameters are used to specify the detection capability of mass spectrometers used for gas analysis: the limit of detection (LOD) and the sensitivity. Although somewhat related, these two parameters describe two important but different features of the instrument. The sensitivity of the instrument is generally given as the expected signal when a known amount of sample is analyzed. For residual gas analyzers operating in the electron impact mode, the typical units are detector current per unit of pressure (A mbar\(^{-1}\)). This quantity should be specified for each detector, because more than one may be used on the mass spectrometer. For Faraday cup detection this quantity tends to be around $10^{-3}$ A mbar\(^{-1}\). Because an electron multiplier detector can easily provide gains of $10^4$–$10^5$, it is not uncommon to see sensitivity in the range of 1–200 A mbar\(^{-1}\). The sensitivity is dependent on the analyte to be measured and its ionization cross-section. For instrument comparisons one should use the same gas (typically nitrogen), detector, ion source, and electron emission current when specifying this quantity, or provide a range of sensitivities. The detector current per analyte gas concentration (e.g. A ppm\(^{-1}\) of N\(_2\)) is another way of expressing this quantity. Table 1 provides typical sensitivities for common process analyzers.

The LOD of the instrument is a measurement of the minimum quantity of analyte that can be measured statistically above the background noise of an instrument. The units are typically partial pressure of the analyte (e.g. mbar of H\(_2\)O), although minimum concentration of the analyte in a particular gas is also widely used (e.g. ppm of H\(_2\)O in argon). This quantity is also dependent on the instrument arrangement, and instrument parameters should be very similar when attempting to compare instruments. Typical values of LOD for instruments with Faraday cup detection and electron impact ionization are $10^{-12}$ mbar of Ar and ca. 1 ppm Ar in N\(_2\). Electron multipliers will lower these quantities by a factor of $10^3$ to $10^{14}$ mbar and 1 ppb. The atmospheric pressure ion source can be extremely sensitive for some gases, bringing these quantities down to 1 ppt. Furthermore, the use of special inlets and preconcentration, such as MIMS, has been shown to give LODs in the parts-per-quadrillion range. In gas leak detection the LOD is given as the minimum detectable gas leak (helium) per unit of time. This is the leak rate or gas throughput of the leak, i.e. standard cubic centimeters per second (cc s\(^{-1}\)) or mbar L s\(^{-1}\). For instruments using a Faraday cup and dedicated towards this type of analysis, this quantity can be extremely low, of the order of $10^{-12}$ mbar L s\(^{-1}\).

### 3.3 Software and Instrument Control

Integration of the mass spectrometer with a process can result in on-line instantaneous decision-making. In complex processes, usually this is not done just from feedback from the mass spectrometer data by itself, but also from feedback from other physical and chemical sensors on-line. The integration of such a complex system may require more sophistication and customization than any one process analyzer data package can provide by itself. Nevertheless, instrument control for most small process analyzers is improving. Implementations of graphical display languages in process analyzers that allow multicomponent software programming, control and data acquisition are quite common. Most analyzers are now available with a number of digital and analog output and input hardware and software features that go beyond the collection of a mass spectrum. The hardware and software are often capable of controlling the immediate processes surrounding the mass spectrometer, alerting the operator to changes in conditions, and controlling a number of analyzer or analysis streams through multiplexing and multitasking. Yet the traditional components to mass spectrometer software that are essential include data analysis routines, spectral libraries, calibration methods, spectrum acquisition, and data logging.
4 APPLICATIONS

4.1 Process Monitoring in Biotechnology

Process monitoring in the different biotechnology industries can be exemplified by a number of areas in which mass spectrometry is being used to make major contributions. These involve the integrity of containers used to seal medical drugs, monitoring of the production of drugs such as penicillin, and monitoring of alcohol production.

4.1.1 Monitoring Container Integrity

The integrity of vials used for drug containment, transportation, and delivery is critical to the pharmaceutical industry. Microbial challenge testing is used to test the lots statistically for sterile conditions. Assuming that vial sterility is lost if a container is flawed or improperly sealed, rather than from the contamination during manufacturing and cleaning, helium leak testing of vials can be used to ensure sample integrity, even after filling and sealing. Kirsch et al. demonstrated that vials sealed under a helium tracer atmosphere with butyl rubber stoppers and crimps, or alternatively sealed under normal conditions and charged with helium tracer, could be monitored for helium leakage with a sniffing probe, using mass spectrometry. The absolute leak rate of the vials was correlated with the squared nominal leak radius (0.5–10 µm) of micropipettes glued to the sides of vials to produce standard leaks for calibration and reference. The minimal observable leak rate under this mode of operation (sniffing) was about 10−6.6 cc s−1. This was mostly attributable to leakage through helium permeation of the rubber septa.

4.1.2 Monitoring of Penicillin Production in a Fermentor

Typically, fermentation processes are monitored using headspace gases. In an interesting application of process mass spectrometry, Hansen et al. have demonstrated the ability to monitor directly the production of penicillin in a fermentor. These authors used MIMS to monitor the consumption of phenoxyacetic acid (POAA) during the production of penicillin V in a 20-L reactor. POAA is the side-chain precursor to penicillin V. Accurate monitoring and control of POAA can result in optimum yield. The fermentor broth was sampled through a microfiltration unit, acidified to 0.1 M HCl, heated to 70 °C, and passed by a silicone membrane. Acidification was necessary for efficient diffusion of the POAA through the silicone membrane and increased sensitivity due to the low volatility of POAA, which boils at 285 °C. A cycle time of 20 min for each measurement was necessary due to the long transfer lines, washing cycle, microfiltration apparatus, and standardization cycle. This duty cycle was sufficient to monitor effectively the production of penicillin V over a production time frame of 150–200 h. The loss of POAA as monitored via the 107-Da ion was due to decarboxylation of the molecule. The loss of POAA has a direct correlation to the formation of penicillin V, as measured off-line via grab samples. The detection limit for POAA was 0.1 g L−1. Alternative techniques for monitoring this process include liquid chromatography and flow injection analysis, but these techniques do not have the specificity that is available with MIMS.

4.1.3 Monitoring Alcohol Production in a Fermentor

Monitoring of ethanol production in a pilot plant has been shown by Johnson et al. using MIMS. These authors used a flow injection system to sample 9000-L reactors. The sampling line from the reactor recirculates at 10 gallons per minute, with 3 mL min−1 of sample from this flow directed to the MIMS system. A silicone membrane heated to 91 °C with a helium jet separator was used to monitor the aqueous sample for ethanol, acetic acid, and lactic acid. An ion trap mass spectrometer was used to scan the mass range of interest. Each sample injection was followed with an injection of a calibration standard to provide continuous calibration of the system. Continuous operation with 3-min cycles between samples and analysis is possible. The system is relatively accurate (2.36%) when compared to standard methods using liquid chromatography, and has excellent precision over periods of days. The system required some daily maintenance in the form of flushing the injection lines twice daily to avoid broth build-up on the lines. Figure 4 shows the simultaneous display of ethanol signal from a process.

![Figure 4](https://via.placeholder.com/150)

mass spectrometer along with other fermentor relative data used to control an ethanol fermentation process.

4.2 Process Monitoring of Flue Gases

Technical incineration presents an excellent challenge for process monitoring. In typical technical incinerators fundamental production processes can take place, e.g. metallurgical production, along with energy production. In these plants it is common to monitor flue gases for CO, CO$_2$, NO$_x$, and total organic carbon (C$_x$H$_y$) production. The CO level, for example, can then be used as an indicator of the burning conditions and the production of possible toxic substances, e.g. polyaromatic hydrocarbons (PAHs) and chlorinated aromatics. Yet no information on the contribution of particular toxic compounds can be obtained and used for control purposes. Typical control parameters in such a system would involve mass flows of air/oxygen, recirculation of exhaust gases, mass flows of the solid and fluid feeds, and temperature profiles in the combustion chambers. Zimmermann et al. have shown the ability to monitor flue gases in a technical incinerator for the presence of benzene, toluene, biphenyls, PAHs, and benzofurans at the parts-per-billion detection level. Furthermore, they demonstrated the ability of these signals to be used as indicators of incinerator conditions showing faults, instabilities, or improper combustion feed processes that can be used for proper control of the incinerator.

Monitoring of trace components in flue gases poses a particular challenge to mass spectrometry due to the complexity of the gas composition to be sampled, the presence of particulates, condensation and reaction of analytes with the sampling lines, and physical blockage of sampling orifices by tarry substances. Furthermore, the apparatus has to be operated in a physically constrained and harsh environment near the furnaces. Zimmermann et al. solved these problems by employing a rugged and mobile time-of-flight mass spectrometer using resonance-enhanced multiphoton ionization (REMPI). The REMPI process utilizes a laser (KrF excimer at 248 nm, 50 Hz, 10-ns pulses, 10 mJ pulse energy) to select optically the analytes of interest and ionize them. The ionization takes place at the end of an effusive molecular beam inlet into the mass spectrometer. The selectivity of such a system can be very high. For example, at this wavelength (248 nm) only aromatic hydrocarbons tend to ionize, whereas aliphatic hydrocarbons, substituted aromatics, carbonyls, and inorganic gases do not. Furthermore, the ionization is soft, i.e. little or no fragmentation of the molecule is observed. The sampling lines to the mass spectrometer were made out of quartz capillary and tubing and heated to 650 K, to minimize reactivity and condensation in the lines. These authors were able to show the ability of this apparatus to detect parts-per-billion levels of PAHs and benzofurans, and correlate their presence to combustion conditions, as shown in Figure 5. In this demonstration the authors made temporary changes in the optimal combustion parameters: the air supply in the incinerator grate is reduced while the air supply in the post-combustion chamber is increased, resulting in unstable combustion conditions. In Figure 5, the post-combustion malfunction was due to accidentally extinguishing, in part, the post-combustion process. Note the time differential in the observation of the anthracene/phenanthrene signal, which differs considerably from the other species.

Figure 5 The REMPI/time-of-flight mass spectrometer-generated time profiles of benzene, naphthalene, dibenzofuran, and anthracene/phenanthrene during a change of process parameters in a technical incinerator. (Reproduced by permission of John Wiley & Sons, Ltd., from Zimmermann et al.)
4.3 Process Monitoring in the Petrochemical Industry

Process monitoring is used extensively in the petrochemical industry to determine the composition and flow of feed materials and final products. Two typical examples are the production of ethylene oxide and polyethylene.

4.3.1 Ethylene Oxide Production

In the production of ethylene oxide the mass spectrometer will typically determine 10 components simultaneously. These components include feed gases and reaction products from catalytic production. Component concentrations range from parts-per-billion to percentages. Control of this reaction is usually optimized close to its explosive threshold. Monitoring of chlorinated hydrocarbons is important because they can easily poison the reaction. In this system a number of molecules are monitored that contain major ions with isobaric interferences, e.g. ethylene oxide and carbon dioxide at mass 44. Nevertheless, the analytes are easily deconvoluted using minor ion peaks that have no isobaric interferences, e.g. mass 43 for ethylene oxide.

4.3.2 Polyethylene Production

In polyethylene production, light hydrocarbon feed and by-products are monitored with concentrations ranging from a few parts-per-million to percentages. Control of this reaction is usually optimized close to its explosive threshold. Monitoring of chlorinated hydrocarbons is important because they can easily poison the reaction. In this system a number of molecules are monitored that contain major ions with isobaric interferences, e.g. ethylene oxide and carbon dioxide at mass 44. Nevertheless, the analytes are easily deconvoluted using minor ion peaks that have no isobaric interferences, e.g. mass 43 for ethylene oxide.

4.4 Process Monitoring in the Semiconductor Industry

Process monitoring provides the semiconductor industry with a means to detect more effectively the flaws in their process, reduce the amount of scrap material production, and determine more effectively the composition of the end product. All of these factors are critical to cost-effective production. Several examples have been selected from the literature, demonstrating the application of mass spectrometry to semiconductor manufacturing in vapor deposition, ion implantation, plasma-enhanced vapor deposition, and molecular beam epitaxy processes.

4.4.1 Vapor Deposition

Water, nitrogen, oxygen and hydrocarbons cause undesirable effects in the metal grain, reflectivity, conductivity, particles, and adhesion of metals such as aluminum, titanium, and titanium nitride during vapor deposition on wafers. The presence of these gases is indicative of gas leaks in the process chamber and improper removal of the photoresist prior to vapor deposition. Markle et al. have shown the applicability of a micropole quadrupole mass spectrometer to the monitoring of these gases in a physical vapor deposition chamber. Three analyzers were placed on the “clean chamber” and two of the sputtering chambers of this device. Wafers that enter these chambers can be monitored for these contaminants, to partial pressures of $10^{-9}$ mbar. The presence of the contaminants can result in a fault indication that would indicate the need for further removal of photoresist from wafers and/or proper sealing of the chambers.

4.4.2 Ion Implantation

Schneider et al. have shown the ability to determine the presence of normal wafers, wafers with insufficiently cured photoresist, and wafers with no photoresist, during As$^+$ ion implantation processing using a micropole quadrupole mass spectrometer. Ions at $m/z$ 2, 28 and 44 were used to monitor the process. Release of H$_2$, C$_2$H$_4$, and CO$_2$ from the interaction of the ion beam with improperly cured photoresist results in a partial pressure increase of these species that is 1–2 orders of magnitude above what is observed with a normally cured wafer. Furthermore, the lack of an initial burst of CO$_2$ from the wafer at the start of the process is indicative of a wafer without photoresist that has been mistakenly introduced into the system.

4.4.3 Plasma-enhanced Chemical Vapor Deposition

The process resulting in the deposition of nitrogen-rich layers of silicon onto wafer surfaces can be monitored and controlled using mass spectrometry during plasma-enhanced chemical vapor deposition (PECVD). In this technique a mixture of silane and ammonia gases is reacted in an RF plasma. Greve et al. have shown the ability to monitor reactive species in a PECVD system. Because the RF plasma operates at approximately 1 mbar pressure, a 0.25-mm reducing aperture with a differentially pumped chamber is used between the process chamber and the quadrupole mass spectrometer. Reagent gases SiH$_4$ and NH$_3$, along with the plasma power, are controlled as a result of the species being monitored. Nitrogen-rich silicon films are deposited when the conditions are selected such that the mass spectrum is rich in Si(NH$_2$)$_3$ species. The conditions are also selected...
such that SiH₃ and Si₂H₆ species are minimized. Under conditions of high ammonia flow and/or high power, the triaminosilane species become predominant. As has been shown by Smith et al., these conditions lead to the deposition of high-quality, nitrogen-rich films because of the excess nitrogen in the triaminosilane molecule over other silicon species. Thus, a multivariate closed-loop control system can be set up to control the reagent gases and plasma conditions in order to increase the formation of the intermediate species of interest. The process works best when the signal for the intermediate species is abundant and low in noise.

4.4.4 Molecular Beam Epitaxy

Semiconductor capabilities realize much of their advantages due, in part, to the heterojunctions formed between various compositions of compounds formed with row III and V elements and II and VI elements. Precise control of the composition of layers can result in well-characterized epitaxial growth of fixed ternary and quaternary layers, or graded transition layers. Celii et al. have shown that the use of in situ quadrupole mass spectrometers improves the control of epitaxial layers in semiconductors by open-loop calibration with short feedback, or by real-time, closed-loop composition control, during vapor deposition in molecular beam epitaxy. In this work the composition of InₓGa₁₋ₓAs was nearly lattice matched to the InP, and determined with an uncertainty of Δx ~ 0.005 in real-time. For composition monitoring, the In⁺, Ga⁺, and As⁺ ion signals were monitored individually. It was found that the In⁺/Ga⁺ intensity ratio is nearly independent of the As partial pressure in the system. Furthermore, the In⁺/Ga⁺ intensity ratio is indicative of the InGa epilayer composition, as shown in Figure 6. The In⁺/Ga⁺ intensity ratio from the mass spectrometer and the InGaAs composition of the epilayer, as measured by X-ray diffraction, was linear from a composition of 48–58% InAs in InGaAs and a In⁺/Ga⁺ intensity ratio of 1.6–2.3, respectively. This linear relationship suggests that the InGaAs composition can be controlled with the use of quadrupole mass spectrometry over this range. Growth periods of approximately 1 week resulted in epilayers of 1000–2000 Å with good precision. Changing the quadrupole mass spectrometer system, opening the chamber, and the position of the Ga cell used resulted in a change in the In/Ga ratio that would require recalibration and short conditioning before proceeding.

5 QUALITY CONTROL

5.1 Interferences

Interferences in mass spectrometry can be classified as spectral and chemical in nature. Both of these have been covered already to some extent in the previous sections, but it is worth consolidating them. Spectral interferences arise from the inability to resolve two or more analytes due to ions with overlapping mass, e.g. nitrogen and carbon monoxide with molecular ions at a nominal mass of 28. Increasing the resolution of the instrument can provide some relief, but usually at the expense of sensitivity and instrument complexity. Fortunately, most molecules will fragment to some extent under electron bombardment. This fragmentation pattern provides a unique fingerprint for the analyte of interest, and may provide additional peaks in the spectrum that can be used to deconvolute the contributions from each component of an analyte mixture. Conversely, if the analyte mixture is very complex, spectral interferences tend to arise because there are too many overlapping fragment ions and deconvolution becomes complex and inaccurate.

Chemical interferences arise from chemical contamination of the sampling system that cannot be resolved spectroscopically. These can also be due to contamination from degassing of system components, back-streaming of vacuum pump oils, and leaks. If unchecked, chemical interferences will introduce a bias and, often, instability in the measurement. As with most vacuum applications, cleanliness in assembling the system and in its operation is paramount. This may be difficult to maintain in a process application, and is often the “Achilles’ heel” of process mass spectrometers. Nevertheless, with careful...
control of temperature, passivation of surfaces, trapping of pumps, and filtering of process gases, adverse effects can be minimized. Finally, the choice of ion source can be used to minimize chemical interferences. For example, an enclosed electron impact ion source tends to be less prone to contamination by the system’s vacuum components, but tends to have lower sensitivity. Atmospheric pressure ion sources have the least likelihood of contamination from vacuum components, but suffer from wide responses in sensitivity for analytes, depending on the matrix of the sample.\(^{(34)}\)

5.2 Analysis of Complex Mixtures

Several methods may be used for the simplification of complex mixtures of analytes.\(^{(35,36)}\) One method is to simplify the spectra to molecular ions by using different ionization techniques. Field ionization, field desorption, and chemical ionization will produce molecular ion spectra with little, if any, fragmentation and rearrangement ions. These techniques complicate on-line instrumentation and are not readily implemented. Instruments with API, as discussed above, will provide molecular ion spectra with almost no fragmentation. Separating the mixtures using chromatographic techniques followed by mass spectrometric identification, when needed, is probably the most powerful method for mixture analysis. A technique that can be implemented easily with on-line process mass analyzers is the low-voltage technique. Furthermore, limiting the analysis to the determination of groups of similar compounds can be the simplest method. This is referred to as compound-type analysis.

5.2.1 Low-voltage Technique

The approach arises from the fact that there is a region of electron bombardment energy (8–10 eV) that results in the formation of molecular ions with little, if any, fragmentation of the molecule for most hydrocarbons. This is also associated with 5–10 times lower sensitivity, but the spectrum is simplified and can be deconvoluted with some knowledge of the components in the analyte mixture. The main limitation to this technique is the resolution of analyte components with the same nominal molecular mass or isotopic interferences. Not all components can be detected using this technique. For example, although aromatic and heteroaromatic analytes are amenable, paraffins, naphthalenes, alkylsulfides, and some other compounds are not. Other disadvantages include high susceptibility to small changes in the electron emission energy, and the method is not perfect, i.e. some fragments or rearrangement products may persist that can be mistaken for molecular ions.

5.2.2 Compound-type Analysis

This approach is commonly used for the analysis of complex mixtures of hydrocarbons. It takes advantage of the fact that hydrocarbon spectra are very similar within a homologous series. For example, as can be seen in Table 2, paraffins have a number of similar fragment ions, whereas their molecular ions tend to differ by 14 Da (CH\(_2\)) within a continuous series. Thus, the intensities of fragment ions at masses 43, 57, 71, and 85 can be summed to quantitate the total paraffins in a sample. Fragment ions at 41, 55, 69, and 83 are representative of cycloparaffins; 53, 67 and 81 for dinaphthenes, dienes and acetylenes; and 77, 78, 91, 92, 105, and 106 are used for alkylbenzenes. Calibration requires that the gases in the calibration mixture be quite close in composition to the sample. Calibration gases are often prepared from well-separated fractions of petroleum distillates. This form of quantitation can be accurate and precise to within a few percent. The reproducibility is maintained by keeping the ion source conditions such that the ratio of the molecular ion and fragment ions in a pure hydrocarbon gas remains constant.

constant during the analysis. The disadvantages of this technique include the need for prior knowledge of the sample mixture to be analyzed, and it is restricted to samples with similar origin, chemical treatment, and boiling range.

5.3 Principles of Quantitative Analysis

Because the partial pressures of the components in a mixture are directly proportional to their concentrations and to the molecular and fragment ion composition of the spectrum, the intensities of the analyte ions can be used to determine quantitatively the composition of the mixture. The mass spectrum of each of the components in the mixture must be known within the instrumental parameters. The molecular and fragment ions to be used for analysis are selected from the normalized spectra. Normalized intensities are used because absolute intensities can vary widely with instrumental parameters. The ions selected should have high abundance in the analyte spectrum that they represent and should be absent or have weak intensities in the spectrum of other analytes. The sensitivity for each of the components in the sample mixture is determined with calibration gases. A matrix of $n$ analyte components and $n + i$ ions (where $i$ is equal to or greater than the number of overlapping ions in the selection) is formed. Matrix algebra can be used to solve the unknown concentrations in the matrix. Thus, for a two-component mixture with two ions in each mixture Equations (1) and (2) need to be solved:

$$zA_1 + yA_2 = M_1$$
$$zB_2 + yB_1 = M_2$$

where $z$ and $y$ are the weight fraction of the two components in the mixture, $A_1$, $A_2$, $B_1$, and $B_2$ are the sensitivities for each ion in the component spectra, and $M_1$ and $M_2$ are the intensities of each of the ions in the mixture spectrum. The matrix expression is given in Equation (3):

$$\begin{pmatrix} z \\ y \end{pmatrix} = \begin{pmatrix} M_1 & A_1 & B_1 \\ M_2 & A_2 & B_2 \end{pmatrix} \begin{pmatrix} A_1 \\ A_2 \\ B_1 \\ B_2 \end{pmatrix}$$

For this simple two-component mixture the matrix solution is given in Equations (4) and (5):

$$z = \frac{M_1B_1 - M_2A_2}{A_1B_1 - B_2A_2}$$
$$y = \frac{M_2A_1 - M_1B_2}{A_1B_1 - B_2A_2}$$

The process can be extended to 30–50 components. Least-squares analysis is the most common quantitation approach. The concentrations are those values that, when multiplied by the corresponding reference spectra and relative sensitivities and then summed for each ion, result in the smallest sum-squares difference between the calculated and the experimentally measured mixture. Other multivariate quantitation approaches include partial least squares, principal component analysis, and chemometrics.

6 COMPARISON WITH OTHER SPECTROSCOPIC METHODS

6.1 Comparison of Technology

A number of other analytical instrumentation techniques are available for process control and analysis that can be used to complement mass spectrometry and in some cases rival its capabilities. These techniques include, but are not limited to, gas chromatography, ion mobility spectrometry, infrared spectroscopy, and chemical sensors. In-depth understanding of these techniques can be found elsewhere in this publication. Other reviews of the literature include that by Walsh and LaPack, who review mass spectrometry principles with a good comparison to gas chromatography and infrared spectroscopy, an extensive review of infrared spectroscopy in process control by Workman, ion mobility spectrometry as it pertains to field applications, and advances in chemical sensors. Although these techniques and others are quite suitable for the monitoring of production processes, much like mass spectrometry they all have strengths and weaknesses. The choice of which technique to use will likely be based on the amenability of the process to be sampled, the analytes to be detected under the required conditions, the specificity required, and the ability of the instrument to stand the physical environment to be monitored. When compared to the above-mentioned techniques, mass spectrometry offers a number of advantages. These include the ability to sample and monitor processes in a vacuum, a high degree of specificity, high sensitivity, a large number of analyte components that can be monitored simultaneously, a fast response time, and very low detection limits. However, other methodologies are worth considering when looking for a process analyzer.

Infrared and other spectroscopic techniques offer good specificity for analyte components and can be used for trace analysis of contaminants in a gaseous process. Detection limits for trace components in gases are still limited by the observation path length, to at best parts-per-million levels. This method is easily interfaced onto process streams, with the aid of an appropriate window. Because it is completely nondestructive (unlike mass spectrometry and other techniques), the sample stream can be left undisturbed. Thus, the technique
is easily adapted to process lines, especially lines that are at ambient and high pressure. Infrared spectroscopy requires a high degree of chemometrics for spectral deconvolution of mixtures, or a preseparation step. Finally, infrared process instruments are highly reliable and require very little maintenance.

Gas chromatography offers an affordable solution to monitor slowly changing process streams. The method relies on the physical separation of analyte components, based on their boiling point and affinity toward a stationary phase. Detection limits can be quite low for specific target analytes with the right detector, in the order of nanogram to picogram levels. The technique is easily implemented into gaseous and volatile liquid streams at ambient and high pressure. The method is destructive and requires supplies of carrier and detector gases to be available. The gas chromatography columns and injector port can be fouled up easily and require regular maintenance. The method has little or no specificity because it relies on time separation to identify components and a detector-type response for classes of compounds.

Ion mobility spectrometry is slowly emerging as an alternative detection method to mass spectrometry. The methods are related in that they both rely on ion formation, separation and detection. But, unlike mass spectrometry, ion mobility spectrometry separates components according to their drift times in an electrical field filled with a bath gas. The charge, size, and collision cross-section of the molecule with the bath gas determine the time separation of the analyte. Separations happen in the millisecond time-frame, therefore this method has a fast response time. The resolution of the method is quite poor compared to mass spectrometry, therefore separation of complex mixtures is quite problematic. Nevertheless, ion mobility spectrometry can provide some degree of specificity, with very low detection limits for some analytes. Most typical ion mobility spectrometry modules use electron capture ionization, which allows the technique to be quite sensitive (at ppb levels) for molecules with high electron affinity, e.g. oxygenated compounds, phosphorus and sulfur compounds, and halogen-bearing compounds. The instrument is small, requires no vacuum pumps, and can be applied easily to sample ambient pressure and high-pressure processes.

Chemical sensors or “chemical noses” are also emerging as real alternatives to the analysis of volatile streams. These types of detectors are characterized by solid-state electrochemical or transducer-type components that can be integrated easily into small and very inexpensive modules. Each individual module is usually not very specific or has a wide response for a class of analytes. However, with the combination of a number of modules that have different response characteristics, the chemical sensor can be trained to have a specific response to particular analytes.

Detection limits tend to be in the parts-per-million range. The method can be applied easily to ambient pressure and high-pressure processes.

6.2 Business Issues

Of the techniques mentioned above, mass spectrometry is probably the most expensive to implement, due to the cost and complexity of the instrumentation. Nevertheless, mass spectrometers are decreasing in price. Residual gas analyzers can be purchased for $2000–5000, but without the vacuum pumps and other essential hardware necessary for operation. A fully operational analyzer with pumps and computer system will cost $15 000 or more. Customization of the analyzer to the particular application will generally determine the majority of the cost for the installation. Installation of these instruments on the process line will require some control of the surrounding environment, because vacuum pumps must be cooled, and vibration and corrosiveness must be minimized. Nevertheless, mass spectrometers can often provide ultimate sensitivity, exceptional specificity, exceptional detection, and unambiguous identification of unknowns which are often unsurpassed by other analytical instrumentation techniques.

ACKNOWLEDGMENTS

The author appreciates the help and support, in gathering figures and information relevant to this topic, from Peter Scoch and Rick Van Vorous of Pfeiffer Vacuum Technology. Support from the Inorganic Trace Analysis Group (CST-9) at Los Alamos National Laboratory during the preparation of this article is greatly appreciated. Los Alamos National Laboratory is operated by the University of California for the US Department of Energy under contract W-7406-ENG-36.

Near-infrared Spectroscopy in Process Analysis

Don S. Goldman  
Optical Solutions, Inc., Folsom, CA, USA

1 Introduction

Near-infrared (NIR) is a spectroscopic method based upon the absorption of light in the wavelength region between 700 nm and 2500 nm due to vibrations of molecular functional groups in the sample. These spectral features arise from overtones and combinations of the fundamental molecular vibrations of these groups that occur in the infrared (IR) at longer wavelengths. NIR is rich with features arising from vibrations of C–H, O–H and N–H.¹

NIR spectra are acquired by determining the absorbance, A, of light over a continuous range of wavelengths in spectrophotometers or at several specific wavelengths in fixed-filter photometers. Absorbance is defined by Equation (1):

\[
A = - \log \left( \frac{I}{I_o} \right)
\]

where I is the signal from the sample relative to the signal from a reference, I₀. The reference can be an empty transmission sample cell for liquids, or it can be a broadband spectral reflector, such as a white ceramic, for reflectance measurements of solids.

Absorbance is usually linearly related to concentration, following Beer’s Law (Equation 2):

\[
A = \varepsilon C l
\]

where \(\varepsilon\) represents the molar extinction coefficient and C is the concentration of the species, and l is the optical pathlength of light through the sample. For a particular species and fixed experimental set-up, \(\varepsilon\) and l are constants. Letting a constant, \(k = (\varepsilon l)^{-1}\), then (Equation 3):

\[
C = k A
\]

A principal advantage of process NIR over IR is the ability to use fiber optics to transmit light between the instrument and the sample over considerable distance. This permits the instrument, a potential source of ignition, to be placed in safe areas where no flammable vapors exist. Only the fiber optic probe in contact with the sample and the optical fibers that connect to the instrument need be placed in the hazardous location. A disadvantage of process NIR is the characteristics of the spectra, which are typically comprised of broad, overlapping peaks in comparison to IR spectra. This often requires the use of sophisticated data analysis methods that place additional demands upon vendors to provide stable NIR instruments and upon manufacturers to have highly-trained staff, often at the PhD level, for calibration model development, implementation and maintenance.

1 INTRODUCTION

NIR has been traditionally viewed by spectroscopists trained in laboratory methods as a less-than-useful spectral region that exists to fill the gap between the ultraviolet/visible (UV/VIS) and IR regions. NIR peaks are broad, overlapped and much weaker than their IR counterparts. So, why has NIR become so widespread in process analysis?

Interest in NIR grew quickly in the 1980s due to the advent of fiber optics, bright light sources and sensitive detectors. NIR also solved some of the difficult...
sampling techniques characteristic of IR, because NIR optical paths through liquid samples may be millimeters or even centimeters, rather than microns. As a result, first commercial fiber optic spectrophotometers were introduced in the 1980s.

The importance of these developments lies in the ability to bring the sampling interface, a fiber optic probe, safely to the process while placing the electronics (ignition sources) remotely, away from hazardous environments. This also meant that the traditional, time-consuming method of collecting (“grab”) samples and bringing them back to the laboratory for analysis could be replaced by continuous “on-line” measurements without exposing workers to potentially dangerous chemicals. Continuous on-line measurements, in turn, mean more responsive process control for better production yield, less rework of off-target material, improved product quality and enhanced worker safety. It began to change the paradigm by measuring chemistry directly, rather than inferring it from temperature, pressure, flow and fluid level.

For NIR to be accepted, it had to provide reliable instrumentation requiring minimal maintenance. Otherwise, there would be little advantage over the much more widespread, but more maintenance-intensive methods, such as process gas chromatography (GC). Thus, considerable advancements occurred over the next ten years or so to meet the requirement of instrument reliability.

As mentioned above, NIR peaks are generally overlapped. Gone is the isolated, narrow peak common in GC or IR analysis. As a result, mathematical methods using multivariate statistics were often required to analyze the subtle NIR spectral changes present among overlapped peaks. This field of multivariate statistical methods for chemical analysis is known as chemometrics.\(^2\) Partial least squares (PLS) is perhaps the most widely used chemometric method applied to NIR data.\(^3\) These methods became widespread in the 1980s as computers improved.

Furthermore, as smaller NIR spectral changes were analyzed in regions with overlapping peaks using chemometrics, greater requirements were placed on the wavelength stability of the instrument. Changes of less than 0.050 AU are typically analyzed in PLS models to predict chemical variables. A small shift in a NIR peak along the wavelength scale can produce such changes. Therefore, wavelength drift from the instrument could impair a PLS calibration model. Thus, considerable advancements in wavelength stability were made after the introduction of the first scanning fiber optic NIR instruments. This period also saw the introduction of newer technologies based upon different optical techniques, such as Fourier transform near infrared (FT/NIR), acousto-optic tunable filter (AOTF) and photodiode array (PDA) spectrophotometers.

As can be seen from the evolution described above, considerable advancements have occurred from the introduction of the first process scanning spectrophotometers. All of these approaches assume that a complete spectrum is required to solve the analytical problem. Often, that is indeed the case, when many parameters need to be predicted from each spectrum, or when peaks appear in other regions of the NIR spectrum that should not be there (outlier detection). However, this assumption generally comes with a hefty price tag. Many of these process NIR spectrometers systems with probes and fibers cost well in excess of $100,000 (US). In addition, they require personnel with chemometrics expertise, not only in developing the calibration models, but also in maintaining them.

In many instances, however, only a few wavelengths are required to provide an acceptable calibration. Moisture is one example where fixed filter NIR photometers have been commercially available for many years. Today these photometers are designed for use with optical fibers for the same reasons stated above. The method of multiple linear regression (MLR) can be used to select a few wavelengths from a complete spectrum analysis.\(^4\) A photometer can then be configured with optical wavelength filters to match those wavelengths at 25 to 50% of the cost of its full spectrum counterpart, without the need for high-level internal expertise. The danger is that a contaminant will appear at a wavelength not analyzed by the photometer.

The purpose of this discussion is to provide the reader with an overview of fiber optic NIR process analysis, including instrumentation, fiber optics, probes and mathematical methods.

2 NEAR INFRARED SPECTRA

Spectra of gasoline shown in Figure 1 illustrate the characteristics of NIR spectra described above. These

![Figure 1 NIR spectra of gasoline.](image-url)
spectra represent transmission of light through a path-length of 1 cm of gasoline. C–H overtones occur in the 1100–1200 nm region. Aromatic contributions give rise to the secondary peak near 1150 nm, with premium gasoline showing greater absorbance due to its greater aromatic content. The larger peak centered near 1200 nm arises from C–H, CH2 and CH3 groups. The region between the 1300 in 1500 nm represents combinations from C–O–H. Note the small changes in absorbance and subtle changes in the shapes of the peaks throughout these regions. Nevertheless, PLS models of NIR spectra in this region are used to predict the octane number of gasoline on-line in real-time to better than 0.3 units at blending facilities. They can also predict many other components of gasoline at the same time that are important in refinery production, such as various additives.

NIR is commonly used to measure water and moisture due to their relatively strong absorption. For example, NIR is commonly used to measure trace amounts of moisture near 1900 nm, as shown in the spectra of tetrahydrofuran in Figure 2. These spectra show successive additions of 1000 ppm water. The 1900 nm region is unique to molecular water, whereas the region near 1450 nm can represent O–H from both water and hydroxyl. Note that contributions from water in Figure 2 near 1450 nm are present, but are much weaker than the peak at 1900 nm.

NIR reflectance measurements have been widely used for solids in food, agricultural, textile, pharmaceutical and other industries. Unlike the transmission of light through clear liquids described above, reflectance measurements are strongly influenced by particle size, uniformity and size distribution of the sample. Thus, much of the evolution of NIR reflectance has been directed towards mitigating these physical effects using larger areas of illumination, taking the average of many measurement points and using computational corrections. The NIR spectrum of wheat flour is shown in Figure 3. The vertical axis is commonly reported as $-\log(1/R)$ in reflectance spectra, rather than absorbance, where $R$ is reflectance. In the spectrum of wheat, moisture is again analyzed in the 1900 nm region, and protein is measured in the region near 2100 nm.

### 3 DATA ANALYSIS

#### 3.1 Partial Least Squares

PLS is a powerful, multivariate quantitative method that is commonly used to predict properties from NIR spectra. Mathematically, PLS uses eigenvectors and eigenvalues to perform a decomposition of the spectral and constituent concentration data simultaneously. The decomposition process is a systematic means to determine the most important variations in the data. PLS uses constituent concentration information during spectral decomposition, which weights spectra containing higher constituent concentrations more heavily. The term “factor” is used to describe a linear combination of spectral data. The first factor that is determined from the
decomposition contains the most variation in the data. This factor is then removed, and a second factor is then determined, which contains a smaller percentage of the overall variation, and so on, all guided by the constituent concentrations. When it is said that a particular solution is obtained with a “three factor” model, this means that the three most important factors explain a sufficient amount of the overall variation in the system, which results in an acceptable calibration. Each factor still contains information from each wavelength in the spectrum, some weighted more heavily than others. Thus, the dimensionality of the problem has been reduced from perhaps 1000 nm of data to three factors. By eliminating less significant factors, PLS is eliminating variations in the data that do not add useful information in establishing a calibration.

PLS reconstructs a spectrum that represents the predicted constituent value. This predicted spectrum is subtracted from the actual spectrum to determine spectral residuals. Spectral residuals are important in outlier detection to ascertain whether the model prediction is believable, i.e. whether the spectrum of the unknown fits within the calibration set used to construct the model.

Disadvantages include the high level of expertise needed to understand and use PLS programs, expertise that many companies lack. Outlier detection may become too sensitive, arising from other factors, such as probe fouling, particles present in the sample and temperature variations in the sample. These problems may lead to spectroscopic anomalies not accounted for in the calibration model. On the other hand, learning of these problems will probably lead to better on-line measurements.

3.2 Multiple Linear Regression

MLR attempts to select a set of wavelengths from the calibration samples that minimizes the sum of the squares of the residuals between the predicted and actual concentrations. All possible combinations of wavelengths are quickly examined with the computational power found in most personal computers today to find the best set. Tests can be used to determine if adding additional wavelengths to the model is statistically significant.\(^4\)

One of the tendencies in using MLR is simply to find the set of wavelengths that produce the “best” fit. This may not be the best strategy, because it may be strongly influenced by noise in that particular data set. User guidance is important in arriving at a robust solution. For example, restricting the wavelength search to regions in which a particular species is known to absorb may prevent the computer from finding a wavelength in a less important region, such as an absorbance valley, or in a region with an extremely small absorbance variation. A leave-one-out approach can also help to determine the robustness of an MLR calibration model. A variety of other statistical parameters can help determine the quality of an MLR model. The shape and pattern of residual plots (actual vs. predicted values) may aid in removing outliers from calibration models.

In addition to the wavelengths selected by the MLR model, more wavelengths can be added to a process photometer to help determine if a sample is an outlier. For example, if several wavelengths are required in the 2000 to 2100 nm region to measure the hydroxyl number in a particular resin, perhaps an additional wavelength can be added at 1150 or 1200 nm where the C–H peaks should be relatively constant. The presence of a contaminant elsewhere in the spectrum not analyzed by the photometer may change the absorbance of these C–H peaks outside their normal absorbance range, which could signify an outlier.

3.3 Calibration Transfer between Instruments

Many manufacturers have multiple processes at each plant site and multiple process plants around the world. As such, they will typically use more than one instrument to measure the same chemistry, presumably using the same model. The problem is that no two instruments are identical. Perhaps the most important difference among instruments is along the wavelength scale. This could involve a small shift of all wavelengths or a change in the wavelength spacing signifying a change in wavelength resolution. As pointed out above, spectral residuals in PLS models can increase quickly even with small absorbance changes over a broad wavelength range that can result from such changes. It becomes impractical to calibrate each new instrument with all of the original calibration samples, which sometimes number in the hundreds. Therefore, calibration transfer methodologies have been developed to help install and adjust models in new instruments without having to re-run all calibration samples. Many commercial PLS software packages now include a calibration transfer module for this purpose. However, their success is apparently quite variable, and it is quite common to hear that calibration samples have been re-run on new instruments.

4 FIBER OPTIC INSTRUMENTATION AND REQUIREMENTS

4.1 Scanning Spectrophotometers

Scanning process instruments rely upon projecting light from an optical fiber or a bundle of optical fibers onto a diffraction grating. The grating disperses the light into its constituent wavelengths. It is mechanically rotated such that a narrow group of wavelengths is sequentially allowed to pass through a narrow slit. In pre-dispersed
instruments, monochromatic light passing through this slit is sent to the sample through a fiber optic cable. The light returning from the sample is then directed to an optical detector. Conversely, in post-dispersed instruments, light is sent directly to the sample and the returning light from the fiber optic cable is directed to the grating where it is dispersed, and passes through a slit placed before the optical detector. Various means are used to relate the position of the grating to the expected wavelength that corresponds to a given signal in constructing a NIR spectrum. The need for faster collection times places a significant burden upon moving the grating quickly and knowing which wavelength corresponds to a particular signal. This is particularly important because PLS models generally required sub-nanometer wavelength stability over time.

4.2 Fourier Transform Spectrophotometers

The process FT/NIR spectrophotometer is an amplitude division interferometer. It is based upon the original Michelson interferometer or one of its derivatives. In all cases, a beamsplitter is used to separate the incoming light beam into two beams, which are later recombined, focused into an optical fiber and sent to the sample. One optical path in the interferometer is kept constant and the other is varied by some mechanical means. An interferogram is produced upon recombining the beams, which contains all the wavelengths in the spectra. Applying a Fourier transformation to the interferogram results in a frequency spectrum (wavenumbers, cm$^{-1}$), which is readily converted into a wavelength spectrum (nm = 10$^{-7}$ cm). There are a variety of ways by which one optical path is varied, including a moving mirror, moving optical wedges, and moving both reflectors in tandem. These developments focused upon issues present in the process environment in contrast to the laboratory, such as the effects of mechanical vibration and large temperature fluctuations. FT/NIR instruments have a “multiplex” advantage over scanning instruments, as well as greater wavelength resolution. The “multiplex” advantage, like the PDA discussed below, means that all wavelengths are analyzed at the same time. The greater wavelength resolution is useful in some applications, but is not particularly required for the generally broad peaks found in the NIR. For hot process samples, blackbody radiation is generally eliminated when taking the interferogram. However, FT/NIR technology has a moving part and can still be prone to vibrations in spite of the design advancements.

4.3 Acousto-optic Tunable Filters

In contrast to scanning instruments, AOTF does not require a moving part. Rather, light is directed into a crystal of TeO$_2$. A high-frequency acoustic wave in the radiofrequency range is coupled into the crystal by the use of a piezoelectric material bonded to the crystal. These acoustic waves quickly propagate through the crystal, interact with the broadband light and generate two monochromatic beams of light, each polarized in a different direction. In essence, the crystal is being made to act as a transmission grating controlled by changes in atomic spacing due to acoustic wave propagation. Either of these monochromatic beams can be used as a source of NIR light, coupled into an optical fiber and sent to the sample. Wavelength switching is very fast compared with scanning instruments, and the AOTF can be programmed to select any sequence of wavelengths. Hence, more time can be spent on specific peaks or in regions of interest, and less time need be spent in spectral regions containing little or no useful information.

4.4 Photodiode Array Spectrophotometers

The PDA is perhaps the most intuitively obvious way of acquiring NIR spectra. A compact, linear array of detectors is placed at an appropriate distance from a diffraction grating to analyze the complete sequence of wavelengths. Thus, light in a narrow spectral region continuously impinges on its own detector element is the array. The integration time, akin to the exposure time on a camera, is easily adjusted to optimize signal-to-noise. PDA has been the latest technology to develop due to the more recent availability of NIR detector material. Although silicon PDAs have been commercially available for some time, they can only be used below about 1000 nm. This region is comprised of even weaker, more overlapped vibrational peaks from higher order overtones than those shown in the previous section. Weaker NIR peaks, in turn, require longer optical paths for liquids and are not particularly practical for reflectance from solids other than for color. The more recent availability of indium—gallium—arsenide (InGaAs) detector material makes the PDA more useful for NIR analysis. InGaAs PDAs currently cover the range from 900—2200 nm. The PDA detector is sealed in an optical enclosure and cooled thermo-electrically. Each photodiode detector in the array is multiplexed and amplified electronically. As with AOTF, PDA is extremely fast, and is able to collect and average a large number of complete spectra in a fraction of a second without moving parts. Another advantage over lead sulfide (PbS) detectors traditionally used in the NIR is the superb low-light sensitivity of InGaAs for highly absorbing liquids or reflectance from solids. Their disadvantage at present is the high price of the detector, although they have decreased by nearly 50% since 1990.

4.5 Fixed Filter Photometers

Traditionally, fixed filter photometers capable of analyzing multiple NIR wavelengths worked by passing light
through a sample cell within the instrument. The sample is continuously extracted from the process and pumped through this cell. Light is then passed through a rotating wheel containing a number of optical interference filters. Interference filters allow light only within a narrow wavelength range, typically 10–20 nm wide, to pass. Different wavelengths are selected in this way and rotated in front of a NIR detector. Thus, traditional photometers had a moving part and still extracted the sample from the process to the instrument. More recently, fiber optics have been integrated into photometers to gain the advantages described above. Also, by using beamsplitters and multiple detectors rather than moving filter wheels, the most recent process photometers have eliminated all moving parts and allow all detectors to analyze their wavelength simultaneously, as in the PDA. This is a subtle, but important point. In process analysis, the sample continuously moves past the fiber optic probe. By analyzing all wavelengths on the same volume of sample at the same time as it moves through the fiber optic probe, potential “process noise” can be eliminated. By adding a microprocessor, process NIR photometers can use multiple wavelengths and MLR in a broad range of applications.

4.6 Fiber Optic Multiplexing

Fiber optic multiplexing is another important technological advancement for process analysis. It permits several fiber optic probes to be sequentially analyzed with one instrument, thereby decreasing the cost per point of analysis. One means to accomplish this is to use a pair of angled reflectors at opposite ends of a rotating shaft inside the multiplexer. Light is brought into the center of one side toward the axis of the shaft, reflected up along a rotating arm and back out the same side into another fiber optic cable connected to the first probe. Thus, there is a central fiber optic connection and several connections around the periphery of a circle. Light returning from the probe is connected to the opposite side of the multiplexer at a similar position on the periphery of the circle, reflected down to the shaft and reflected again into the central connector and out toward the detector. Rotating to the next position on the circle examines the next probe, and so on.

One fiber optic cable can be routed from one side to the other of the multiplexer bypassing a fiber optic probe. This can be used to measure changes in the instrument over time, such as the aging of the light source, and correct the spectrum from each probe accordingly. This is particularly important if such changes have different magnitudes in different spectral regions. This procedure is commonly referred to as “internal” referencing. It is generally needed in process systems because the reference spectrum is taken with an empty transmission probe or a reflectance standard with a reflectance probe. It is stored in the computer and used for many months. Therefore, the internal reference is used to make corrections when process probes cannot be removed frequently from the process and re-referenced.

4.7 Enclosures for the Process Environment

The presence of process NIR spectrophotometers and photometers in the production environment pose fire or explosion hazards if flammable vapors exist. Therefore, NIR process equipment will likely require special enclosures to reduce or eliminate such risks to personnel and equipment. Hazardous area classifications for North America are divided into Class, Division and Group under the NFPA 496:1993 standard. Common classifications for NIR analyzers are given below;\(^{6}\)

4.7.1 Class 1, Division 1, Groups B–D

Areas where flammable gases and vapors are likely to be present continuously, intermittently or periodically in quantities sufficient to produce explosive or ignitable mixtures, including most chemical vapors (other than acetylene, Group A). Enclosures for these environments can be bolted and sealed, or may have a pressurized purge systems that will turn off the instrument if pressurization is not maintained. European Zones 0 and 1 correspond to Division 1.

4.7.2 Class 1, Division 2, Groups B–D

Areas where flammable gases and vapors are likely to be present to produce explosive or ignitable mixtures only in the case of accidental rupture or breakdown of equipment, including most chemical vapors (other than acetylene, Group A). Enclosures for these environments generally have pressurized purge systems in which the instrument will continue to function, even if pressurization is lost. Loss of pressurization can be detected electronically by process control computers systems, although such connections require intrinsic safety barriers. European Zone 2 corresponds to Division 2.

4.7.3 General Purpose, NEMA 4

Although there are variety of NEMA classifications, NEMA 4 is a commonly used enclosure, where 4 represents watertight (weatherproof). A comparable European designation would be IP65.

5 FIBER OPTICS AND FIBER OPTIC PROBES

The advancements in NIR instrumentation described above would required concomitant advancements in fiber
Flow probes are placed between pipes anywhere from piping. Liquid is often pumped through side streams. These probes are designed for slip (side) streams, which are fast bypass liquid streams with smaller diameter than the main stream. They are commonly used in process analysis to continuously monitor reactions in a reactor. Typical probes can withstand temperatures up to 250 °C and 1000 psi (7 MPa). They are more expensive than flow probes by 50–100%, but they are often the only way to access the process piping.

### 5.1 Transmission Probes

#### 5.1.1 Insertion

Insertion probes are typically long metal rods, 18–25 mm (¾–1 in) in diameter and commonly 9–28 cm (6–12 in) long that are designed to be inserted through ball valves into the side of a reactor or into a large pipe. These probes generally transmit a collimated beam of light through the sample only once between sapphire windows placed in a cutout along the side of the probe near the tip. Collimated light is used to eliminate the potential effect on the spectrum due to changes in the refractive index of the liquid sample. Light is coupled into and out of the probe with fiber optic connectors. Light propagates within the probe along one side either using a fiber optic cable or a hollow reflective tube. It is reflected back up the other side of the probe using a retroreflector placed inside the probe at the tip. Light passes through a collimating lens and through the sample between the windows and then out of the probe to the analyzer. The windows are generally braze into the probe and the braze material may be subject to chemical attack. There always seems to be one application in which the chemistry attacks the braze material. Some use primary o-ring seals for the windows selected for specific chemical compatibility rather than using a braze. Insertion probes must be removed using the ball valve for cleaning and re-referencing. These probes can typically withstand temperatures up to 250 °C and 1000 psi (7 MPa). They are more expensive than flow probes by 50–100%, but they are often the only way to continuously monitor reactions in a reactor. Typical optical paths range from 1 to 20 mm for transmission probes in the NIR.

#### 5.1.2 Flow

These probes are designed for slip (side) streams, which are fast bypass liquid streams with smaller diameter piping. Liquid is often pumped through side streams. Flow probes are placed between pipes anywhere from (¾–1 in) (6–25 mm) in diameter in which the liquid flow passes through the metal body of the probe. Most rugged flow probes have sapphire windows and primary o-ring seals. Collimated light passes across the liquid moving through the probe perpendicular to the direction of flow. These probes generally have a removable clean port. The side stream can be closed off and drained using valves and sample ports, and the clean port on the probe can be removed for easy cleaning of the optics. Thus, the probe does not have to be removed from the process piping. This is important because, in hazardous environment, optical fibers are contained in conduits attached directly to the probe making frequent removal difficult. The sample can also be conditioned in side streams by heat-tracing to control sample temperature and by filtering to remove light scattering particles or bubbles that would adversely impact spectroscopic measurement. Side streams allow samples to be readily taken for laboratory analysis in order to adjust the calibration of the instrument over time.

### 5.2 Reflectance Probes

Reflectance probes are used similar to the insertion probes described above. They generally use multiple fibers to provide larger areas of illumination and greater intensity for collection of light reflected from the sample. Many configurations are commercially available. The simplest involves placing six optical fibers around one central fiber within the probe. The six fibers are bundled into one optical fiber generally connected to the light source, and single fiber is connected to the detector. The fibers in the probe are generally placed in a 1/4 in (6 mm) diameter metal tube containing a sapphire window at the tip. Various techniques are used to minimize the specular component of the diffuse reflectance from the sample and to minimize stray light inside the probe. Other designs utilize larger diameters and have reflective tubes inside, thereby eliminating the presence of fibers within the probe. This permits higher temperature operation. Reflectance probes can be inserted directly into light scattering liquids or into moving streams of powder. Sample presentation at the probe tip for solids is critical. Variations in packing efficiency of the powder against the probe will strongly impact the quality of spectral data. Using fiber optic reflectance probes on-line becomes more difficult for larger solids, such as pellets, simply because the optical fibers limit the image spot size relative to the larger size of pellets. Illuminating larger areas of solids from a distance has been used to analyze for moisture for many years. However, these methods do not rely on fiber optics.

### 5.3 Internal Reflectance Probes

Attenuated total internal reflectance (ATR) is used to measure the liquid phase in multiphase samples containing light scattering centers, such as particles in slurries and bubbles in foams. This method has been used successfully in the IR and the ultraviolet (UV) where the absorption from vibrations and electronic transitions,
and highly polished. Single fibers are generally used over epoxied into metal connectors with their ends exposed also be reinforced by metal coils. Fibers are typically jacketed by a variety of protective materials that may which is easily measured with most NIR detectors. Fibers are much weaker and require thousands of reflections to produce acceptable spectra. One way has been found to accomplish this in the NIR, and that is to shrink the thickness of the internal reflectance element to less than one micron and propagate light through this thin film. This thin film is deposited on a glass surface at the end of a fiber optic insertion probe that is placed in contact with the liquid sample. Thousands of internal reflections occur resulting in a spectrum of the liquid phase in the slurry approximately equivalent to a transmission cell with a path of 3–4 mm. The danger in using ATR in the process is that surfaces can become coated and prevent the ATR probe from sensing changes in bulk chemistry.

5.4 Fiber Optics
The optical fibers available for NIR are multi-mode with diameters generally ranging from 200 to 600 microns. They have a silica core with a doped silica cladding, and a polyamide protective coating. There are two types of fibers used with process analyzers, referred to a low-OH and high-OH. High-OH fibers are used in the UV/VIS because they are less prone to solarization (darkening) upon exposure to UV light. Their higher OH content precludes their use for most NIR applications. Low-OH fibers are used in the NIR to minimize absorption due to the fiber itself in the important O–H regions near 1450 nm and above 1900 nm. A lens is used to inject light into the optical fiber to match its typical acceptance angle of 22°. Light follows a variety of paths through the fiber and is only attenuated slightly over long distances. For example, a typical low-OH fiber at 1600 nm only absorbs about 0.08 AU over 100 m, which means that about 83% of the light is transmitted in each direction to the fiber optic probe, or about 69% round trip. Assuming that the fiber optic probe itself transmits 40% of the light and the sample in the probe, in turn, transmits 40% of the light, that leaves 69% times 40% times 40%, or about 11%, which is easily measured with most NIR detectors. Fibers are jacketed by a variety of protective materials that may also be reinforced by metal coils. Fibers are typically epoxied into metal connectors with their ends exposed and highly polished. Single fibers are generally used over longer distances due to cost, whereas fiber bundles are used over short distances. Fiber bundles may have tens or even hundreds of fibers contained within the cable. Fiber cables are generally secured in manufacturing facilities within conduits or in cable trays. Care must be taken not to bend fibers too sharply. Typically a minimum 6 in (9 cm) bend radius is specified.

6 ORGANIZATIONAL ISSUES
Although this article has focused upon the technologies involved in process NIR, it may not be obvious to many readers that successful implementation is more dependent upon corporate organizational issues than upon the instrumentation itself. This is a bold statement.

Process analytical chemistry is highly multi-disciplinary. It involves process engineers and chemists who know what they want to measure and where it can be measured, instrumentation technicians who will maintain the instrument, technology gatekeepers who will look for new instrumentation, analytical chemists who perform the laboratory chemical analyses upon which the NIR calibration is based, and researchers who perform the initial feasibility studies. There are also specialists in data communication, safety and others. Therefore, the person who identifies the instrument may not be the same person who calibrates it, or who is the eventual “owner” of the equipment. The person who develops the NIR calibration may not be responsible for its maintenance over time.

Companies that establish the means for this “internal technology transfer” among their various groups will have the greatest likelihood of achieving the benefits of on-line NIR technology described above. A fundamental requirement for such success is visible and consistent upper management support of process analytical chemistry. Without this, workers will be less inclined to “stick their neck out” and try a new technology that may help their organization to improve product quality more efficiently. This is difficult in an era of corporate downsizing where concern for job security does not inspire workers to take such risks. This is also made difficult in most instances because these instruments are often installed in existing, profitable processes. Their benefit is not “all or nothing”, but rather incremental, which is harder to justify. Sometimes, catching a major process upset early pays for the entire cost of the instrument. In other words, if everything worked perfectly there would be no need for NIR instrumentation in the first place. Lastly, for companies just beginning to consider such on-line measurement technology, it is important to build advocacy with early success by judicious selection of the first application. Selecting a pricey nine-probe NIR spectrophotometer and developing the world’s most sophisticated PLS model for the first
on-line NIR application is probably not the best approach to build this advocacy.

With diligence and a consistent focus, NIR process instruments can help manufacturers achieve the objectives of improved product quality, reduced manufacturing costs and enhanced worker safety.

Nuclear magnetic resonance (NMR) spectroscopy is an experimental technique based on the interaction between nuclear magnetic moments and an applied magnetic field. The nuclei emit and absorb energy at a specific frequency that is proportional to the applied magnetic field. Magnetic resonance imaging (MRI) is the term used to describe the spatial resolution of NMR signals within a sample. NMR/MRI may provide information on the weight, chemical composition, physical properties, and structure of a sample. NMR is a noncontacting and noninvasive measurement. NMR and MRI are suitable for use in process control and have been applied to polymer processing, food processing and refinery processes. The response is linear from the detection limits of approximately 10 ppb to 100%. The accuracy of the technique depends on the signal-to-noise ratio (S/N), which is a function of the sample size, applied magnetic field strength, the radio-frequency (rf) coil and the spectrometer hardware. Typical accuracy of the technique is 0.5% for measurements of composition and 1–5% for viscosity. NMR cannot generally be applied to magnetic or highly conductive materials.

1 INTRODUCTION

Process analytical chemistry is a rapidly expanding field. The need to enhance production efficiency and maximize profits has provided a strong driving force to improve the control of industrial processes. This has resulted in efforts to develop new types of process sensors based on traditional analytical instruments. There has been considerable success in developing on-line analytical instruments based on gas or liquid chromatography, infrared spectroscopy and mass spectrometry, and flow injection analysis.\(^1\) Until recently there has been limited success in developing a process analyzer based on NMR. Several companies now market on-line or in-line analyzers based on NMR.

NMR has many properties that are advantageous when considered for process control applications.\(^4\) These advantages include a noncontacting and noninvasive measurement. The NMR signal is directly proportional to the number of nuclei in a specific sample volume. The signal is linear from the detection limits (~10 ppt) to 100%.\(^4\) The signal can be used to measure multiple quality factors like concentration and droplet size. The instrument has no moving parts. Highly specific information can be obtained by analysis of only one nucleus \(^1\)H, \(^13\)C, \(^19\)F, \(^11\)B, \(^23\)Na or \(^31\)P or a combination of nuclei utilizing the same instrument.

Application of NMR for on-line or in-line sensing requires consideration of the influence of motion, temperature and environmental factors. For nuclei with a spin angular momentum, the net magnetization \((M)\) developed in the sample after it is placed in an external magnetic field\(^5\) is given by Equation (1):

\[
M = \frac{N\gamma^2\hbar^2 I(I+1)}{3kT}H_0
\]

Where \(N\) is the number of nuclei, \(\gamma\) is the magnetogyric ratio, \(I\) is the spin quantum number, \(H_0\) is the external magnetic field.
magnetic field strength, $\hbar$ is the Planck constant, $k$ is the Boltzmann constant, and $T$ is the absolute temperature. The time development of the magnetization is most often well approximated by an exponential time constant the spin–lattice relaxation time ($T_1$). The proportionality of the nuclear magnetization to temperature and time has important implications in the design of on-line NMR sensor systems.

Temperature effects can either be dominant in the measurement or unimportant. For sensing based on relationships to relaxation times or other temperature sensitive parameters, precise control of the sample temperature is necessary. Temperature control is required in the measurement of solid-to-liquid ratio in fats and oils. However, in many applications using low resolution or high resolution spectroscopy the temperature has a negligible effect on the method and temperature variations can be ignored. This is often the case in measurements of the moisture content of products where the field homogeneity of the magnet dominates the decay of the signal.

The influence of motion on a NMR signal is manifest through changes in the effective relaxation times and signal intensity. The influence of motion on the relaxation times is expressed as Equations (2) and (3):

$$\frac{1}{T_1^{\text{observed}}} = \frac{1}{T_1^{\text{static}}} + \frac{1}{\tau} \quad (2)$$

$$\frac{1}{T_2^{\text{observed}}} = \frac{1}{T_2^{\text{static}}} + \frac{1}{\tau} \quad (3)$$

Where the inherent relaxation times are designated with the superscript static, the relaxation times observed during flow are designated with the superscript observed, and $\tau$ is the lifetime of the nuclei in the measurement zone. If the sample flows at the same rate through the measurement zone the lifetime will be given as the measurement zone volume divided by the flow rate. Thus, motion of the sample will cause a decrease in the observed time constants for relaxation. This change in relaxation times will result in an increase in the linewidth of the NMR spectra. The sample will also have a residence time in the magnetic field. For full equilibration this should be at least five times the largest spin–lattice relaxation time observed in the sample. If full equilibration is required for the measurement method, the design of the magnetic field, rf probe and sampling system will be critical to successful implementation.

2 HISTORY

NMR spectroscopy is now over 50-years old and has become one of the premier experimental methods for studying the structure and dynamics of condensed matter. The first successful experiments were performed independently by Bloch and Purcell in 1946. Soon after the first experiments, a NMR spectrometer was modified for process control. Nelson, Reilly and Savage developed a NMR spectrometer to record the proton spectra from a flowing stream at 30 MHz. The proton spectra were recorded every 6 s in a 3-mm diameter glass tube. The spectrometer was coupled to a pilot plant process. To overcome the problem of achieving equilibration of the sample, a reservoir was located within the magnet. This demonstration of using a NMR spectrometer for process control was successful however; the authors noted the high cost of the sensor. Additional applications with magnetic fields capable of resolving chemical shifts include measurement of viscosity and fat content in meat.

The largest number of applications that have been proposed, tested and implemented are based on low-cost permanent magnet systems. Two groups, Tri-Valley Research and The Southwest Research Institute made major contributions to the early development of these systems. These NMR analyzers were primarily applied to the measurement of moisture content in agricultural and food products.

Several companies have begun to offer industrial NMR process analyzers. Auburn Instruments offers a permanent magnet-based system to measure the properties of polymers. Foxboro Instruments has a spectroscopy-based system oriented towards applications in the oil and chemical industry. An MRI based whole-body clinical system has been modified by a Intermagnetics General Corporation/SMIS Ltd joint venture for final product quality monitoring of a packaged food.

3 APPLICATION MODES

NMR sensor systems may be designed based on the properties of the NMR equipment or on the requirements of the measurement. The deciding factor is the result of the economic analysis and feasibility testing. Constraints applicable to common types of NMR/MRI systems will be presented in this section. The component that most often defines the range of applications of a NMR/MRI sensor is the magnet. The properties of the magnet, field strength, field homogeneity, and homogeneous volume are the most important for defining the range of applications for a particular NMR/MRI system.
3.1 Low Resolution

The term low resolution indicates that the NMR equipment has a magnet with a low-magnetic field strength. NMR systems with a low-magnetic field strength (<0.5 T) are not usually used to separate the signal from different components by analysis of the frequency content of the signal. This type of analysis has also been referred to as wide-line NMR. Discrimination is usually based on the rates of signal decay governed by either the spin–lattice relaxation time or the spin–spin relaxation time or the magnitude of the signal at specific times. NMR relaxation times characterize the interactions between the nuclei and their surroundings in the sample. The spin–lattice relaxation time characterizes energy exchange between the nuclei and the surrounding lattice. The spin–spin relaxation time ($T_2$) characterizes the loss of phase coherence between the magnetic moments of the nuclei. If the magnet field in a low-field spectrometer has a high homogeneity the signal from different components can be resolved based on the difference in the frequency response from each component. There have been few applications of these types of system with a highly homogeneous magnetic field of low strength. The applications are similar to those discussed in the next section on high resolution systems.

Low resolution NMR units are often of a small enough size to be located easily on a laboratory bench top. The costs of such a unit are also modest in comparison with commercial research grade NMR systems. Low resolution systems have been available since the early 1970s. These systems have been widely used in the chemical, medical, agricultural and food industries.

The signal from low resolution NMR is analyzed in the time domain. The main focus has been on the use of data from the free induction decay (FID), spin-echo or pulse sequences Carr–Purcell–Meiboom–Gill (CPMG) (as shown in Figure 1). The different types of analysis can be classified into the ratio, absolute, or relaxation time methods.

Ratio applications are where the intensity of the signal at two different times during the signal decay is used to form a ratio (see Figure 1). This ratio is then directly related to the quantity of interest, for example, a moisture content or a solid–liquid ratio in oil. The advantage of this type of measurement is that it is independent of the weight of the sample and the sample volume does not need to be constant from sample to sample. Absolute methods are based on the value of the signal at a specific time. For this type of measurement it is critical that the rf probe have a high homogeneity over the entire sample. The volume of material tested must be precisely controlled from sample to sample and during calibration of the instrument. Relaxation time applications use either the initial amplitude from one component in a multicomponent material or the relaxation data itself to correlate with a quality parameter like moisture content. Simple rf probes like those used for the ratio measurement are appropriate unless a weight-normalized measurement is needed.

Details of the most common experiments used in low resolution NMR analysis are given in Figure 1.
The FID (Figure 1a) is often used for moisture content measurement or determination of the solid–liquid ratio in fats and oils. The initial signal following the rf pulse is proportional to the total number of protons in the sample. The time decay of the solid and liquid fractions differs by several orders of magnitude, $T_2$ for solid fats is between $10^{-20}$ and $T_2$ for liquid fats is ~100 ms. Therefore, if the signal amplitude at the initial time is compared with the amplitude a short time later, the solid to liquid ratio can be calculated. This is because both the solid and liquid phases contribute signal initially and after a short time only the liquid component contributes to the signal (see Figure 1a), the solid signal having decayed completely. Deadtime in commercial NMR instruments ranges from 7–10 µs after the end of the rf pulse. The liquid signal is generally recorded at 70 µs after the rf pulse. Equation (4) is the expression for the liquid fraction corrected for the deadtime of the NMR receiver:

$$\text{liquid fraction} \quad \frac{w_{\text{L}}}{w} = \frac{L}{L + fS}$$

Where $f$ is a correction factor that accounts for the decay in the NMR signal during the time prior to signal acquisition. The other experiments, Figures 1(b) and 1(c), can be used to measure oil content in seeds or moisture and oil content in confectionary products.

### 3.2 High Resolution

The most important difference between low resolution NMR systems and high resolution NMR systems is the strength of the applied magnetic field. The higher magnetic field permits the separation of spectral components based on their frequency response. A high resolution NMR system is capable of producing data such that nuclei in different local chemical environments can be identified based on their frequency response. The proton resonance frequency for on-line applications of high resolution NMR is between 30–100 MHz. The variation in the frequency response is referred to as the chemical shift. The chemical shift is reported in parts per million referenced to a standard. The most common standard used for proton spectra is tetramethylsilane (TMS). Table 1 demonstrates the range of proton and carbon chemical shifts for different chemical structures. Figure 2 is the proton spectrum taken at a proton resonance of 85.5 MHz from an intact durian fruit. The largest peak is from water; the next two are from sugar and oil components, respectively. The types of data shown in Figure 2 are used to calculate the ratio of the components or a concentration of one of the components, for example, sugar content. Components with at least 1 Hz difference in their resonance frequency are resolvable, as long as the magnetic field homogeneity is significantly better than 1 Hz and the resonance lines are narrow.

### 3.3 Particle Size Measurements

NMR is one of the premier methods available for measuring the self-diffusion coefficient of molecules. The pulsed field gradient (PFG) NMR technique, as developed by Stejskal and Tanner has been widely applied for measuring the effect of molecular diffusion on the NMR signal in a spin echo experiment. When a system has a heterogeneous structure, the translational motion of diffusing molecules is strongly influenced by the internal structure of the sample. In a confined geometry, the maximal extent of diffusional displacement is limited by the size of the confinement. For example, the geometry and the dimension of the internal droplet boundaries restrict the diffusion of oil molecules within an emulsion droplet. This effect is referred to as “restricted diffusion” and has been studied extensively. For molecules bounded by a sphere of radius $a$, the signal attenuation in a PFG NMR experiment is given by Equation (5).
Here, $a$ is a constant dependent upon the NMR equipment, $\rho_i$ is the nucleus density of component $i$, $TE$ is the time-to-echo, $b$ accounts for the effective value of field gradients and $PD$ is the predelay. Equation (7) forms the quantitative basis for contrast in the intensity in MRI data. If the sample is undergoing translational motion this can also be used to encode contrast in the intensity of the MRI data.

\[
M(t) = K \sum \rho_i \exp \left( -\frac{TE}{T_2i} \right) \times \left( 1 - \exp \left( -\frac{PD}{T_1i} \right) \exp(-bD_\gamma) \right)
\]
4 NUCLEAR MAGNETIC RESONANCE APPLICATIONS

There are a large number of reports on the application of NMR/MRI to characterize the composition, physical properties, and defects in both liquid and solid samples. Many of these have been tested with the goal of determining the feasibility of process control. In Table 2 are listed some of the most common material characteristics that can be measured with NMR/MRI. Listed in Table 3 are examples of applications of these characteristics in different industries. Specific examples for each mode of application will be discussed next.

4.1 Moisture Content

Compared with other sensing methods, NMR offers significant advantages in determining the moisture content of a processed material. Table 4 describes the six most common moisture-sensing techniques that are most often used industrially. In comparison NMR has no inherent limitations, with the exception that the capital expense is usually higher. The NMR method provides a measure of the total moisture and can provide continuous on-line measurements.\(^{10,11}\) In addition, NMR does not require the assumption of a uniform distribution of moisture within the sample, instead measuring the particular nuclei of interest (hydrogen in the case of moisture) throughout the bulk material. In other words, low resolution NMR measures the total hydrogen content regardless of the distribution and can distinguish between aqueous and nonaqueous forms. This is very advantageous compared with other sensing techniques,

especially with microwave methods, where inhomogeneous distributions can seriously affect the accuracy of the measurement.

NMR has been used to measure moisture in a variety of both food and nonfood products, including chocolate, crackers, potato chips, packaged soups, paper and wood pulp, composite structures, soap and detergent, and coal. Pearson et al. have described the application of NMR to measure moisture in aluminum oxide (17) and in agricultural products (18,19).

One method of determining the moisture content using NMR is to ratio two points from the time domain signal (often called the FID). The points ratioed are separated in time by several hundred microseconds. This method has several advantages in moisture determination. These include:

- The measurement relies on a ratio which is unaffected by the size of the signal. This method is therefore insensitive to the packing density of the sample volume since air voids in the material will only affect the size of the NMR signal and not the ratio.
- The measurement is extremely fast. The calculation of the moisture content from the signal is very simple, so that it is possible to make as many as 500 measurements per second in most materials.
- The measurement is simple and hence the NMR apparatus required is minimized.

Historically many correlations between NMR parameters and moisture content have been performed by first calculating a relaxation time or a ratio of intensities at different times in the decay (13). Chemometric techniques have been shown to provide better predictions of quality factors when applied to the NMR time domain data directly (19,20). Improvements in the area of data processing promise to expand the number of economically viable low resolution measurements.

4.2 Quality Evaluation

The potential uses for quality monitoring with MRI are very broad. MRI images can be produced with a contrast that provides specific information on physical properties, product structure, contaminants, safety, stability, processability and consumer acceptance. An on-line quality evaluation sensor has been designed using a MRI system. The MRI uses a permanent magnet and individual cases of the final product are inspected on a conveyor belt (Figure 4). The measurements are implemented using a modified multislice multiecho pulse sequence. This approach permits the entire three-dimensional sample to be investigated rapidly. The system is designed to inspect 100% of production (The Foxboro Company, http://www.industrialnmr.com/index.htm (July 30, 1998)). Critical to the success of process MRI/NMR units is the design of software to diagnose sensor performance.

The diagnostic software developed for this application includes the monitoring of the strength of the magnetic field, the homogeneity of the magnetic field, gradient strength and the operation of the conveyor belt. The sensor is started with a few simple commands shown in Figure 5. During normal operation the screen displays information on the product and sensor diagnostic results. Specific diagnostics include monitoring the magnetic field strength, homogeneity, gradient strengths and conveyor operation. The software automatically corrects for instrumental drifts such as slight changes in magnetic field strength or magnetic field homogeneity.

Variations in the geometric design of the magnet have been demonstrated. For example a single-sided NMR magnet has been implemented by the Southwest Research Institute for the measurement of product moisture content (10,11). The single-sided system has obvious advantages when applied to conveyor systems both in terms of magnet cost and flexibility of implementation.

4.3 Spectroscopy

The major advantage of using high resolution techniques in comparison to low resolution techniques is that the quantity of different components can easily be separated using the spectral data. This type of data is shown in Figure 2 and the two major constituents are oil and water. The application of high resolution techniques to quantify oil content, moisture content and sugar content in intact fruits, vegetables and foods is straightforward (9,22,23). Quantification of component concentrations permits grading of food items. For example in US standards for grades of fresh produce the soluble solids content
is a key parameter to be evaluated (i.e. juice from cantaloupes should not contain less than 9% soluble solids). Chen et al. have studied the feasibility of grading fruit and determining fruit maturity using high resolution spectra. The basic procedure is to record the proton spectra, ratio the spectral peak areas (or peak heights) of the different components and compare with standard destructive analysis. Results obtained from avocado maturity, soluble solids content and sugar content generally have correlation coefficients of 0.9 or better.

The feasibility of making this type of measurement on moving fruit has recently been demonstrated. Spectra were acquired measuring the maturity of avocados on a specially designed conveyor belt. The conveyor was constructed entirely from nonmagnetic parts (see Figure 6). Fruit speed on the conveyor varied between 0–0.25 m s\(^{-1}\). Potential problems such as sample vibration and misalignment of the NMR rf coil were investigated. None of these factors significantly influenced the correlation between NMR spectral analysis and destructive tests.

A commercial sensor is now available to measure the spectra on a liquid side stream (http://www.foxboro.com/nmr/index.htm (July 30, 1998)). The Foxboro Company has recently introduced an on-line, continuous flow-through NMR sensor (see website above). The sensor is capable of multiple analysis of chemical constituents and physical properties. The NMR system is designed to be used on-line in petroleum refineries to perform reformate analysis, crude oil analysis, characterization of naphtha streams, acid alkylation analysis, gasoline analysis and distillate analysis (see website above). This sensor has been installed in a refinery since 1995. The
system incorporates flow-through rf probes and software with multiple calibration techniques. Advances in the construction of permanent magnets have been critical to the stability and operation of this sensor. 

High resolution NMR has also been combined with high-performance liquid chromatography. Techniques using both stopped-flow analysis and continuous flow analysis have been developed. Specific devices are available to interface the NMR spectrometer with either a gas or liquid chromatography system. Combined NMR and liquid chromatography has been used to detect chemical intermediates with short lifetimes and chemical equilibria in batch processing of chemicals.
4.4 Polymer Characterization

Auburn International (http://www.auburnint.com/ (July 30, 1998)) has developed an on-line sensor designed to measure polymer material properties. The sensor is capable of making multiple analyses including density, melt index, copolymer content, solubles, and rubber content. Comparisons of the measurement of the melt index and xylene solubles between the sensor and laboratory procedure are shown in Figure 7(a). NMR may also be used to quantify the properties of gas phase systems, properties such as density can be measured as shown in Figure 7(b). Measurements on polymers can be made on both solid (powders or pellets) and liquid polymers. The sensor is based on a low resolution type NMR spectrometer that has been redesigned for process applications (Figure 8).

4.5 Subsurface Earth Hydrocarbon Characterization

A NMR device has been developed and is now used routinely as one of a number of instruments for characterizing the properties of hydrocarbon reservoirs in subsurface earth formations. The spectrometer has been built to operate at temperatures up to 175 °C and at speeds of up to 10 cm s⁻¹. The NMR sensor is based on measurements performed outside the spectrometer. The measurements are therefore acquired in a very inhomogeneous magnetic field and hence are limited to amplitude and transverse decay of the proton signal. The pulse sequence employed is the CPMG sequence with phase cycling.

The NMR measurements are used to quantify the porosity of the formation, the hydraulic permeability, the fraction of fluid that will not flow (fluid trapped by capillary forces or physisorption on clay materials), and the physical properties of the hydrocarbon. The most important physical property measured is viscosity. The viscosity is measured through a correlation between the distribution of $T_2$ and hydrocarbon viscosity. (24)

5 EMERGING APPLICATIONS

5.1 Viscosity Measurements

Rheological properties are an important factor relating to processability, safety, stability and quality of many products. Viscosity has been one of the most frequently measured physical properties in NMR/MRI sensor applications. The most frequent method for prediction of viscosity has been through the correlation between changes in relaxation times and solution viscosity. The dependence was predicted and demonstrated in the late 1940s. (25) This method has been applied to a variety of substances including particulate suspensions, polymers and foods. (27) This simple technique is often adequate for process control; however, only a single viscosity at one shear rate or a Newtonian viscosity is obtained. In the
processing of many polymers, foods and fluids exhibiting complex rheology more information is required. For example, in polymer processing the determination of molecular weight distribution is an important parameter and for this determination the shear viscosity versus shear rate over several decades of shear rate is needed. A new MRI based technique has been designed to obtain this data on flowing process streams.\(^{28,29}\)

The method is based on measuring both the fluid velocity profile \(v(r)\) and simultaneously the pressure drop in the pipe \((\Delta P/L)\). The shear rate \(\gamma(r)\) is calculated directly from the velocity profile \(\gamma(r) = \frac{d(v(r))}{dr}\) and the shear stress is calculated from the pressure drop \(\sigma(r) = -(\Delta P/2L)/r\). The radial variable is eliminated by combining the equations for the shear stress and shear rate and this permits calculation of \(\sigma(\gamma)\) or \(\sigma(\gamma)/\gamma\), (as shown in Figure 9). The viscosity data resulting from a single combined measurement of the velocity profile and pressure drop ranges from a shear rate near zero to the maximum at the tube wall \((r = R)\). This procedure is essentially an extension of standard capillary viscometry and the shear rate range that is normally obtained is from \(10^0 - 10^3\) s\(^{-1}\). Additional rheological information may also be obtained from the velocity data, including apparent wall slip velocity,\(^{30}\) and apparent yield stress.\(^{31}\) The advantages of this MRI-based technique are:

- It can be performed on-line or in-line with only minor modifications to the process line.
- It is applicable to dense suspensions and multilayer systems.
- The same equipment can provide additional quality measurements like component concentrations, or melt index.

5.2 Defect Detection

Defects such as voids and foreign bodies are frequently detectable using MRI data.\(^{32}\) MRI can provide a map of the proton density in a material. This density map may be used to monitor a product for defects. For example, in food processing MRI data can be used for pit detection in fruit, quality grading of cheese and inspection of fresh fruit and vegetables for damage.\(^{27}\) The type of damage that can be detected in fruits and vegetables includes insect damage, bruises, frost damage, voids, internal structure collapse, and the presence of mold.\(^{32}\) Use of echo planar imaging techniques would enable rapid data acquisition compatible with process line production rates. For objects with a symmetric shape it is sufficient, depending upon the defect, simply to acquire the proton density as a function of position in one direction, a projection. This is demonstrated for detection of pits in processed cherries in Figure 10. The presence of a pit in the cherry changes the expected proton density intensity map. Based on the shape of the profile the presence of a pit can be detected using the projection data.\(^{33}\)

6 INSTRUMENTATION CONSIDERATIONS

Since the late 1970s NMR has experienced tremendous growth in the clinical and biological arenas. This interest, combined with the immense increase in electronic and computational power, has greatly spurred the development of MRI and spectroscopy. As a consequence, the application of this technique to process analysis is rapidly expanding. The principal components of an NMR/MRI system are summarized in Figure 11.
PROCESS INSTRUMENTAL METHODS

Figure 10 MRI two- and one-dimensional images of whole and pitted cherries acquired while the cherries were moving at 250 mm s⁻¹.

Figure 11 Principal equipment components of a NMR/MRI spectrometer.

Rigorous constraints govern where and how the NMR/MRI system can be located and what type of apparatus will be preferred for a specific application. The choice of the appropriate NMR system is complex and several parameters should be taken into account, the most significant considerations are the magnet, gradient/rf coils and process modifications.

6.1 Magnets

The optimum magnetic field strength will depend upon the application under consideration and the information required. In general the field strength available in NMR process analyzers will provide a proton resonance frequency <100 MHz. The choice of field strength depends on the application under consideration: spectroscopy, imaging or low resolution. Choosing the magnetic field strength may be complicated in process analysis where complex materials are to be investigated and both spectroscopy and imaging information are desired.

Relatively high magnetic fields are essential to magnetic resonance spectroscopy for two basic reasons: chemical discrimination and S/N. Although some applications at low field have shown feasibility for water/fat selectivity, the study of more fine detail (i.e. ethanol) or less sensitive nuclei (i.e. ²H, ¹³C, ³¹P) favor higher magnetic fields. Magnetic fields producing proton resonance frequency >100 MHz are easily reached only with superconducting electromagnets.

Superconducting electromagnets consist of coils of superconducting materials enclosed in a cryostat. These superconducting materials, when held below a certain temperature (critical temperature) reach almost infinite conductivity. Hence, the materials can carry high currents indefinitely (if maintained at low temperature) producing a very stable and strong magnetic field. Commercially available superconducting magnets operate at liquid helium temperature (4.2 K) and their strength ranges generally from 0.3–11.4 T. The capital cost of the superconducting magnets is high and they require regular refilling with cryogenic liquids. These two factors are generally not considered compatible with process analysis applications. Also, at high fields the intrinsic heterogeneity (internal susceptibility contrasts) of the sample can cause dramatic effects such as broadening of linewidths and decrease in the relaxation times making some applications unworkable. When magnetic field gradients are required, measurements with this type of magnet suffer from strong artifacts resulting from eddy currents created by switching the current in the gradient coils. Using “shielded” gradient coil designs where a second set of coils shield the metallic structures within the magnet from the pulsed magnetic fields generated by the switching gradients can minimize eddy current generation.

Considerable effort has gone into permanent magnet design for process applications. Permanent magnets are available in a large number of configurations. These can be made as single-sided systems for conveyor applications, with a cylindrical cavity for pipe and conveyor applications or as two parallel plates with the sample passing between the plates. Permanent magnets are made of an assembly of individual magnetized bricks of alnico alloys or rare earth, often mounted around an iron yoke to increase field strength. The principal disadvantage of such magnets is their weight (up to 30 tons for large bore systems). Field strength can range
generally in less than 100 values, current in the coils must switch on and off rapidly, standard imaging techniques do not require such large reach values of gradient up to 1500 G cm which carry intense electric currents (up to 50 A) to coils are made of large and thick copper conductors variety of ways in high resolution spectroscopy. These displacement of molecules. Gradients are also used in a way to encode local spatial information in the NMR experiment high power rf pulses have to be transmitted to the sample while weak NMR signals from the sample have to be detected with a sensitive receiver. The NMR probes must have their field perpendicular to the main magnetic field, constraining the possibilities of probe design.

The static magnetic field strength, the electronics utilized in the spectrometer and the sample itself dictate the SNR achievable for a particular application. It is the design and construction of an adequate rf coil that is critical in achieving that dictated SNR. In this sense, the quality of the transmitting and receiving rf coils determines to a large extent the performance of the NMR apparatus. An extensive literature exists on coil theory, design and construction. More detail concerning designs presented in this section can be found in the review on rf coils by Link. rf Coils can be roughly separated in two categories: volume coils and surface coils. Volume coils are wound around the sample and have the ability to excite and image the whole volume of interest. One of the most popular and efficient probes is the solenoid and its optimized variants (Figure 12a). Unfortunately this design often conflicts with geometric constraints (sample size, magnets with axial main field) and high frequency applications (its high inductance make this design nonoptimal for some applications over 100 MHz). Several other designs have been proposed to compensate for these limitations.

A successful and easy-to-build coil is the optimized slotted tube (also known as Alderman-Grant) resonator which consists of two conductive sheets supported by a cylindrical structure (Figure 12b). More sophisticated designs such as the Bird Cage coils (composed of lumped elements) have become very popular because of their ability to excite and image the whole volume of interest. One of the most popular and efficient probes is the solenoid and its optimized variants (Figure 12a). Unfortunately this design often conflicts with geometric constraints (sample size, magnets with axial main field) and high frequency applications (its high inductance make this design nonoptimal for some applications over 100 MHz). Several other designs have been proposed to compensate for these limitations.

Unfortunately this design often conflicts with geometric constraints (sample size, magnets with axial main field) and high frequency applications (its high inductance make this design nonoptimal for some applications over 100 MHz). Several other designs have been proposed to compensate for these limitations.

As their name indicates, surface coils are positioned as close as possible to the sample to ensure high sensitivity (Figure 13). Their utilization is generally combined with a volume coil that is used to excite the sample homogeneously while the surface coil is used as a local
Significant effort has been devoted to the development of rf superconducting devices. Owing to their low resistivity those devices should increase the SNR of the experiments substantially. Although to date only prototypes have been presented it can be expected that superconducting rf coils will gain importance in the near future.

6.4 Process Modifications

6.4.1 Process Design

It is imperative that the design of the process to be monitored is fully compatible with the NMR experimental constraints, which means basically the use of nonmagnetic parts. Figure 6 shows an example of a fruit conveyor designed and constructed to monitor fruit quality on-line. Common materials used are glass, plastics, and nonmagnetic metals such as copper, aluminum or stainless steel. Since rf fields have to penetrate the sample, the container or holder must be made of nonconductive material such as glass, plastic or ceramic. For low-pressure and low-temperature applications glass-lined probes are adequate.\(^8\) As the temperatures and pressures increase, Teflon\(^9\), Kel-F\(^9\), or other nonmetallic materials are required. Monitoring canned (iron or aluminum) products or studying the flow in metallic pipes is thus unrealizable unless the rf and gradient coils are placed inside the metallic structure and the metallic structure is nonmagnetic.

Properties of the sample must also be considered when developing a sampling system.\(^8\) For proper loading of the sample narrow bore tubes with diameters between 3–10 m are adequate for low-viscosity fluids. For higher viscosity fluids, fluids with particulates and solid samples, larger tube diameters or piston mechanisms may be required.\(^8,9\) Filters may be required upstream of the magnet to prevent the deposition of magnetic materials from the process in the rf probe and magnet assembly.

6.4.2 Site and Environment

The site and environment of the process analyzer should be reviewed carefully. The first consideration is to study the effect that the fringe magnetic field (magnetic field outside the magnet) may have on devices and activities in surrounding areas. The influence of fringe fields is best controlled by design of the magnet/sensor system. Reciprocally, the effects of devices and activities that could potentially affect the NMR system operation must be quantified. The system must also be isolated from unstable power lines or rf sources that operate at similar frequencies.
6.4.3 Data Sampling, Acquisition and Processing

Most NMR instruments for process analysis are PC-based and offer flexibility and expandability. High-speed digitizing boards (usually up to 10 MHz 12-bit dual-channel) are readily available and cover the majority of applications for high speed NMR. In real-time applications, digital signal processing (DSP) boards permit hundreds of different complex operations at the “hardware” level. Processing routines such as two-and three-dimensional FFTs (fast Fourier transforms), binarizing, edge detection, and convolutions are readily available with high-performance independent processors substantially decreasing the computation time. Comprehensive software is furnished with any NMR system and specific applications can be developed with multipurpose software such as StatView®, Matlab® or IDL®. Applications of chemometric techniques for model building have been demonstrated to improve the performance of the sensor systems.120,21

6.5 Basic Troubleshooting

When the SNR of the NMR experiment falls below an acceptable point or no signal is detected, basic items can easily be tested to isolate the problem. A basic “troubleshooting chart” has been developed by Traficante39 and a more detailed discussion is given by Fukushima and Roeder.40

First, a standard sample should be inserted into the system and the signal acquired. Next, all the cables and connections that are accessible should be inspected and tested. It is also important to note that any changes in the environment (electronic/mecchanic equipment) can interfere with a NMR experiment. After external possibilities are tested, the field homogeneity should be checked. A simple one-pulse experiment will provide a good idea of the field homogeneity and indicate if shimming is needed. It is useful to examine the Fourier transform of such signal (it can be only noise) to determine if external signals are affecting the measurement. External noise can be due to improper shielding of the system. If these steps do not isolate the problem, the rf coil should be tested. The coil must be properly matched (usually to 50Ω) and tuned to the right frequency: this procedure is always accessible and provided by the system manufacturer. If suitable tuning or matching cannot be obtained, the rf coil may require servicing. If the problem is still not apparent, the high-power performance of the probe must be tested. Positioning a small pick-up coil (single loop) in the vicinity of the rf coil and monitoring the pulse with an oscilloscope, during high power operation tests the rf probe performance. If the pulse collapses and a nonrectangular shape is observed, it is possible that the rf probe needs maintenance (e.g. faulty or dirty capacitors, defective soldering points).

However, the high power needs to be checked separately (connecting it to an oscilloscope through an appropriate attenuator). If all the points above have been checked and the problem persists the receiver network should be examined.

7 METHOD DEVELOPMENT

In the development of NMR/MRI methods for process analysis, several features of the sample and measurement interaction should be addressed. In NMR/MRI measurements, the signal is a voltage acquired in time from a specific volume. The S/N can be influenced significantly by placing a sample in different regions of the volume or partially outside the volume. When comparing amounts of different materials in NMR spectra, the integration of the peak areas needs to be converted for differing molecular masses and variations in density. Consider the measurement of the percentage of ethanol in whiskey.41

Integration of the OH and CH2 peaks and correction for the OH resonance from the ethanol hydroxy proton yields a percentage ethanol that is lower than the expected value. Additional adjustments to the integration values for the mole ratio and density corrects the calculation and the expected result is obtained (40% v/v).41

The temperature of samples should be controlled and be reproducible. Relaxation times are often strong functions of both temperature and composition and signal intensity is inversely proportional to temperature. Changes in composition and processing conditions and the influence of these changes should be incorporated into the analysis.

ACKNOWLEDGMENTS

We appreciate the helpful discussions and comments from Dr T. Skloss, Dr I. Pykett, Dr C. Nicholls and Mr Vaughn Davis. The assistance of Ms S. Sadikin and Ms E. Northheimer in preparation of the figures and text is gratefully appreciated.

Raman Spectroscopy in Process Analysis

M. Anne Leugers
Dow Chemical Co., Midland, USA
Elmer D. Lipp
Dow Corning Corp., Midland, USA

1 Introduction

Raman spectroscopy is a laser light scattering measurement in which changes in the frequency of the incident light as a result of scattering from a sample are measured. Raman spectroscopy is generally used to measure vibrational energy levels of molecules and is complementary in that regard to infrared (IR) spectroscopy which measures vibrational energy levels by the absorbance of IR radiation. Although more difficult in the past to perform than IR spectroscopy, recent technological changes have made Raman spectra easier to measure and with better sensitivity. Currently, Raman spectroscopy has about the same general sensitivity as IR spectroscopy and, in many instances, much simpler and more flexible sampling requirements. Raman spectroscopy is particularly useful for molecules containing some form of unsaturation, various inorganic species, halogenated materials, and homonuclear diatomic gases (such as H₂, N₂, and O₂) which are transparent in the IR.

Increased application of Raman spectroscopy for a variety of problems has led to its use for on-line measurements in industrial manufacturing processes. These applications generally involve remote placement of the spectrometer from the process and the use of fiber optics to take light to the sampling points in the process and return scattered light to the spectrometer for analysis. The use of fiber optics is one of the strengths of Raman spectroscopy for these applications. An additional strength is in the probe designs for focusing the laser light and collecting the scattered light at the sampling point. Probes have been designed which are insertable into processes and can withstand high temperature and pressure, or which can operate from a distance through a viewing window, thus completely avoiding physical contact with the sample. This allows Raman spectroscopy to function in difficult environments where other techniques cannot gain access. Sampling intervals with Raman spectroscopy are generally in the seconds to minutes time regime, well within the range needed for meaningful process control.

The disadvantages of Raman spectroscopy often stem from absorbance of the incident laser light by the sample or impurities in the sample. This can lead to sample decomposition or burning if the absorbance is significant due to the amount of power under the focused laser light. Less severe absorbance can lead to fluorescence (absorbance followed by emission) which can easily produce enough light to obscure the Raman scattering. Some samples may not have distinct enough spectral information for the problem at hand and Raman would be ruled out on that basis.

Raman will compete against IR (both mid- and near-) for many process applications. Mid-IR offers a high level of spectral information, but poor options for fiber optics. Near-IR has much less spectral information for most problems, but good choices for fiber optics. Raman offers the best of both IR approaches, having a high level of spectral information combined with good choices for fiber optics. Specific problems need to be evaluated on an individual basis as to whether Raman, mid-IR, or near-IR offers the best approach using knowledge about the spectral information present by each technique and the sampling options for on-line monitoring of the process.

1 INTRODUCTION

Raman spectroscopy is a laser light scattering measurement which provides information about the molecular structure of a material. Raman scattering refers to the portion of the scattered light which has undergone a wavelength shift from the wavelength of the incident radiation. The energy associated with the wavelength shift corresponds to electronic, vibrational, or rotational energy levels in the molecule. The most common use of Raman
spectrum is to measure energy shifts associated with vibrational energy levels, although rotational transitions for small molecules such as $\text{H}_2$ are also routinely measured. Raman spectroscopy is useful for determining the chemical composition and certain physical properties of samples for both qualitative and quantitative information, and often provides additional or complementary information to its more common counterpart, IR spectroscopy.

Industrial applications of Raman spectroscopy are relatively sparse when compared to IR spectroscopy. For many years Raman spectroscopy was difficult to perform and suffered from low sensitivity. New technologies such as reliable large-frame laser systems, improved optical filtering designs, more sensitive detectors, and fiber optic sampling probes converged in the early and mid-1990s to make Raman spectroscopy easier to perform and with much better sensitivity. This led to a dramatic increase in the use of Raman spectroscopy in industrial laboratories, which in turn led to the development of Raman spectroscopy for direct on-line analysis of industrial manufacturing processes. Recent references containing material discussing Raman as a process analytical tool include a review article on this topic, a biannual review of Raman spectroscopy, and a book about applications of Raman spectroscopy. It is no exaggeration to say that Raman spectroscopy is now a burgeoning technique which may soon become as widely dispersed as IR spectroscopy.

2 ANALYZER COMPONENTS

The typical design of a fiber optic Raman analyzer is shown in Figure 1. The major components are a laser, fiber optic cables and probe, spectrograph, and detector. The fiber optic cables and probe are an especially important part of the analyzer as they both deliver light to the sample and collect scattered light for analysis. All probes currently in use have a 180° backscattering geometry. A review article on this subject describes many different probe designs. The spectrograph eliminates the residual Rayleigh scattering and disperses the Raman scattering by wavelength across the charge-coupled device (CCD) array detector. A computer then processes the data and displays spectral or other output.

2.1 Probes

Fiber optic probes for Raman spectroscopy are referred to as filtered or unfiltered depending upon whether an optical filter is present within the probe. The earliest designs were unfiltered, and one of the first used a single fiber for both transmitting and collecting light. Despite the complete overlap between excitation and collection fields of view, this design was inadequate for most applications. Sensitivity was low because the single collection fiber gathered too little of the Raman scattered light, and the spectra were fraught with silica artifacts resulting from laser light reflected back into the collection fiber. Therefore, a multifiber probe with different fibers performing the functions of transmitting and collecting, and with some provision for removing silica bands, must be used.

Multifiber probes without filters are frequently referred to as bundle probes. These probes must be inserted into the sample being measured. They are very effective with clear liquids but are generally not useful for solids or liquids which are highly scattering due to the presence of suspended solids or bubbles. A few designs depicting overlap between excitation and collection areas (which ideally is maximized) are shown in Figure 2.

One of the most efficient bundle probe designs consists of a single central illuminating fiber surrounded by a ring of fibers. The central fiber transmits light from a laser to the sample, and the outer fibers collect scattered light and transmit it to the spectrograph. Suppression of silica artifacts is achieved with this type of probe by angling the collection fibers relative to the excitation fiber, and by controlling their spacing. Figure 2(c) shows such a design which was patented by the Dow Chemical Company. The actual probe has six collecting fibers angled around the central fiber. They are fixed in place within a rugged tube and a silica or quartz window tightly seals the end. The Dow Chemical probe has a history of successful process applications, and this includes conditions of high temperature, high pressure, and corrosion.

Another type of bundle probe was developed by Schwab and McCreery who used a close-packed bundle of optical fibers of the same diameter. Bundles of six or 18 fibers naturally form a close-packed cubic geometry and, as such, this type of probe is quite easy to fabricate. By not spacing the fibers, however, the spectra are quite susceptible to silica artifacts from reflected light. This

![Figure 1: Diagram of components in a process Raman analyzer.](image-url)
Figure 2 Diagram of some common unfiltered probe designs showing overlap between excitation and collection areas: (a) one excitation fiber, one collection fiber; (b) one central excitation fiber, several collection fibers; (c) collection fibers angled to increase overlap and suppress silica artifacts; (d) collection fibers beveled to suppress silica artifacts.

Prevents use of windows in front of the fibers except for very thin films which are thinner than the effective field of view. For short laboratory analyses, these probes worked quite well with a polymer film such as Saran Wrap® in front of the fibers. As such, they are unsuitable for process applications.

A third style of bundle probe, developed by O’Rourke and Livingston, also employs six collecting fibers surrounding the central illuminating fiber. The axes of all of the fibers are parallel but the faces of the collecting fibers at the distal end of the probe are polished into a flattened conical arrangement (Figure 2d). This type of collecting fiber geometry allows rejection of reflected light from the window–sample interface and, like the Dow Chemical design, the end can be sealed with a silica or quartz window.

Filtered probes allow complete rejection of Raman silica bands from the fibers. These probes are useful with clear liquids, opaque liquids, solids, and gases, and do not require insertion into a sample but can operate from a distance. However, they are more expensive, are sensitive to alignment of the optical components (and thus temperature), and are somewhat lower in Raman scattering efficiency for clear liquids.

The first filtered probe design was developed by Carraba and Rauh and is shown in Figure 3. The probe employs two fibers, one for transmitting and one for collecting. When the laser light enters the probe it is collimated and filtered with a laser bandpass filter to remove the silica Raman scattering generated in the fiber length. The light strikes the sample and the scattered radiation is collimated, filtered to remove the Rayleigh line (which would excite Raman scattering in the collection fiber), and refocused into the collection fiber. This style of probe provides complete overlap of the excitation and collection fields of view, and this helps to compensate for transmission losses from the numerous optical components. Dilor developed a very similar probe geometry which was also designed to be noncontacting. The lens used at the tip of the probe to focus and collect radiation was of a sufficiently long focal length to be some distance (up to several inches) from the sample. Kaiser Optical has a probe with similar geometry as well. Currently, filtered probes such as these are the most common choice for industrial process applications.

2.2 Lasers and Optical Fibers

Three types of lasers are typically used for on-line fiber optic Raman systems. These lasers are small, rugged, air-cooled, and operate at 115 V. Except for the helium–neon laser, the cost per milliwatt for these portable lasers is quite high relative to large-frame ion lasers. However, large-frame lasers operating at 220 V, 30 A, and 3 gal min⁻¹ of cooling water are impractical for on-line instruments. These portable laser systems all have relative strengths and weaknesses as summarized in Table 1.

2.3 Spectrographs

The three main types of spectrographs used in process Raman analyzers are axial transmissive, Czerny–Turner, and Echelle. The strengths and weaknesses of these spectrograph designs are summarized in Table 2. The holographic filter technology, which is part of the axial transmissive design from Kaiser Optical, is the industry

### 2.4 Detectors

Array detectors have become an important component in Raman spectroscopy. A review article on array detectors for spectroscopy<sup>10</sup> discusses the characteristics of various detectors for spectroscopic measurements. Virtually all commercially available Raman spectrometers employ a silicon CCD detector. The most common type of CCD detector for Raman spectroscopy is the uncoated, front-illuminated CCD detector peaking at roughly 40% quantum efficiency (QE) in the range 650–750 nm. The detectors drop to roughly 1% QE at 1050 nm and 400 nm. Thus, these detectors are quite good for excitation with 500–650 nm laser sources.

One approach to enhancing QE across the visible and into the ultraviolet and near-IR is the use of thinned, back-illuminated CCD detectors. These detectors can range as high as 80% QE at their peak response and can extend the detection range to 200–1100 nm. However, these detectors are still quite expensive and may not be as rugged as the thicker, front-illuminated CCD detectors.
3 RAMAN AS A PROCESS ANALYTICAL TOOL

3.1 Strengths
As a process tool, Raman will compete most frequently against mid-IR and near-IR techniques. The mid-IR generally provides a high level of spectral information, but no good choices for fiber optic probes. The near-IR has good choices for fiber optics, but the spectral information is often limited. Raman combines the best feature of each IR technique by providing a high level of spectral information with good choices for fiber optic probes. An additional advantage of Raman probes is the backscattering collection geometry in the probe tip. There is no gap that the sample must flow through as in mid- and near-IR transmission probes, which is very important for the analysis of viscous polymers and solid slurries. Filtered probes do not need to contact the sample, but may operate from a distance through a sight glass – a very important advantage with corrosive streams. As the information content of Raman spectra is high with individual bands often being baseline resolved (or nearly so), it is possible in many instances to avoid complicated chemometric data handling approaches in favor of much more direct band height or area ratios. These direct methods require much less time and effort to develop and maintain, and they are generally more robust to changes in process conditions which may have occurred since a chemometric calibration was developed.

Modern Raman spectrometers provide sufficient sensitivity for many applications to allow relatively rapid sampling rates, in the seconds to minutes time regime, which is the speed often necessary for meaningful process control. These instruments can be compact and portable, require no special utilities, and are certainly rugged for short-term use. Some on-going applications will provide insight into long-term performance and reliability. Part of the ruggedness of Raman spectrometers is due to the wavenumber stability which results from the presence of only a single moving part – the camera shutter in front of the detector. The other optics in these spectrometers are fixed in position so that they do not move with time, further contributing to wavenumber stability. Another beneficial feature is the ability to multiplex several probes onto a single spectrometer with no moving parts. Most CCD detectors are large enough to be partitioned into separate areas, each of which is large enough to hold an entire spectrum. The laser beam can also be divided into several beams with each beam directed into a separate probe. The Raman scattering from each probe can then be focused onto a portion of the CCD dedicated to that probe. This allows continuous and simultaneous monitoring from several probes with the camera shutter remaining the only moveable part in the system.

3.2 Weaknesses
Compared to mid-IR and near-IR techniques, there are a number of disadvantages as well. Samples that fluoresce are always troublesome. A common approach with fluorescence is to move to longer wavelength lasers, but this sacrifices sensitivity. From a safety standpoint it must always be verified beforehand that a sample will not degrade or burn under the highly focused laser beam. Many of the lasers in use today do not have long lifetimes from a process analysis point of view, so provision must be made for replacing them in a timely fashion. Some important functional groups are weak Raman scatterers, such as OH and NH. Sensitivity among Raman, mid-IR, and near-IR is an issue which must be addressed on a case-by-case basis, as Raman and IR often have complementary spectral features. There is a general perception within the spectroscopic community that Raman is less sensitive than either IR technique. Our feeling is that this perception must be qualified. One reason to avoid dogmatic statements in this area is due to the variety of lasers, detectors, and optical configurations available in Raman spectrometers. This leads to a wide range of sensitivities which can be achieved, and the field is in a rapid state of change with significant new options being introduced each year. This contrasts sharply with mid- and near-IR instruments where components are relatively standardized within each technique and sensitivity among different instruments within each technique is generally comparable. Our experience at this time is that Raman can provide sensitivity which is basically comparable to the mid- and near-IR, provided that instrument components which maximize Raman sensitivity are selected. For good cases, sensitivities in the 100 ppm range are feasible, and 0.1 – 1% is commonly achieved. Many of the advances being made in Raman instrumentation may swing the sensitivity comparison in favor of Raman in the near future.

4 APPLICATIONS

There is a large body of literature dealing with the remote monitoring capabilities of Raman spectroscopy. However, many of these are evaluations done in laboratory settings and the number of process applications in real industrial environments is much smaller. Some of these have been selected for discussion, with the intention of conveying the breadth of process analysis problems to which Raman spectroscopy can be applied.

4.1 Distillation Streams
Industrial distillation processes are used to purify a wide variety of materials. These separations are often very
energy consuming, and precise control of the distillation conditions is needed to enhance the purity of the final material along with minimizing the energy costs. Small improvements in the performance of these columns can have large monetary impacts. Thus, it is not surprising that some of the earliest efforts at process control by Raman spectroscopy were directed at distillation columns.\textsuperscript{(11–13)} These initial efforts focused on three separations: acetic acid and solvent; isopropanol and water; and cumene and cumene hydroperoxide. The first two applications involved a high concentration of water, and hence were difficult by near-IR, whereas the third involved detection of a peroxide group which was basically IR inactive. An insertable probe was used for these measurements, and liquid samples were measured from particular points in the distillation streams. This work demonstrated that Raman could provide sufficient sensitivity and time resolution for meaningful process control of these separations.

Another application of on-line Raman spectroscopy is for measuring the composition of methylchlorosilane distillation streams.\textsuperscript{(14)} These streams consist of various mixtures of methyl- and hydrogen-containing chlorosilane monomers which are being separated by distillation for later use in the production of silicone polymers. Near-IR measurement of these streams was not feasible because several of the species of interest would have been weak or transparent. Raman monitoring of these streams used the Dow Chemical insertable probe\textsuperscript{(15)} which could withstand the corrosive environment caused by residual HCl. The use of Raman in this example takes advantage of the high information content of the spectra along with the capability for faster time resolution relative to current monitoring by gas chromatography. The nine species of interest all have large and distinct Raman bands from SiCl and SiH moieties, and the data was collected at 5 min intervals. Figure 4 shows the concentration profile with time for a two-component stream where large changes in stream composition are followed in very great detail.

![Figure 4](image)

\textbf{Figure 4} Concentrations in a two-component methylchlorosilane stream showing how the two species fluctuate with time.

### 4.2 PCl\textsubscript{3} Production

An on-line Raman spectrometer has been used to monitor various species during PCl\textsubscript{3} production\textsuperscript{(15)} where P\textsubscript{4} and Cl\textsubscript{2} gas are mixed in a closed reactor. PCl\textsubscript{3} is an additional by-product. This problem could not be addressed by near-IR because all the species of interest are basically transparent in that region. Raman monitoring of this corrosive and hazardous mixture occurred with a probe operating from a distance through a viewing window, thus taking advantage of the ability of Raman spectroscopy to sample noninvasively. Accurately measuring the reactor contents has two important roles in the synthesis of PCl\textsubscript{3}. First, ensuring that excess P\textsubscript{4} is present allows efficient control over the reaction rate as this rate can then be controlled by the Cl\textsubscript{2} feed rate. Second, PCl\textsubscript{3} levels can be monitored. A build-up of this material is to be avoided as it can react with P\textsubscript{4} and interfere with the PCl\textsubscript{3} production. This process had been previously monitored\textsuperscript{(16)} with a Fourier transform Raman spectrometer, but was subsequently changed to a visible laser–CCD system to achieve both higher sensitivity and lower operating costs.

### 4.3 Petrochemicals

Raman monitoring of petrochemicals and fuels has received much attention because Raman has a generally high sensitivity for aromatic species, and the spectra of related species such as xylene isomers often show distinctive differences. A chromatographic process to separate p-xylene from other aromatic and nonaromatic species has been monitored on-line at four different points simultaneously.\textsuperscript{(17)} One spectrometer and four fiber optic probes were used for this application. The laser beam was divided into four parts using a beam splitter, and each of the four beams was then directed into a separate fiber optic probe. The CCD detector was electronically partitioned into four separate areas, and the Raman scattered light from each probe was directed onto one of these four areas. The combined use of a beamsplitter and partitioning of the CCD allowed one instrument to monitor four different points simultaneously with no moving parts, thus minimizing instrumental drift and producing a very robust instrument for process environments. Raman monitoring of this process was capable of controlling the process by following several chemical species over wide concentration changes.

A number of other chemicals or properties of petroleum fuels have been studied by Raman spectroscopy for potential on-line measurements. Some of these include benzene, octane number, density, and volatility,\textsuperscript{(18)} and a series of papers dealing with oxygen content from ethers and alcohols, benzene and other aromatics, octane number, and Reid vapor pressure.\textsuperscript{(19–22)} Some of these studies were comparisons of Raman with
mid- and near-IR measurements. Raman spectroscopy was found to be a suitable tool for each of these applications, as were mid- and near-IR when they were also studied. Preference for Raman as a process analytical tool in these applications would probably stem from capabilities for noninvasive sampling, multiplexing several streams to one spectrometer, and the higher degree of spectral distinction among some species.

4.4 Syndiotactic Polystyrene Production

An especially difficult on-line application for which Raman spectroscopy has proved successful is for monitoring the production of syndiotactic polystyrene. During the polymerization reaction process, liquid styrene monomer is converted to a free-flowing polystyrene powder which becomes airborne in mechanically agitated reactors. The outlet powder contains significant amounts of unreacted monomer absorbed on or in the particles, and control of this outlet monomer concentration is critical for achieving reliable and efficient performance of the reactor. Spectral measurement of solids suspended in air is a difficult problem because quantitation of results is highly dependent upon the particle size. This problem is more severe with IR transmission measurements than for Raman as a scattering measurement does not require the light to pass completely through the particles. The problem is further exacerbated for transmission measurements when the transparent medium is air, due to the large refractive index mismatch between the particles and air. Consequently, near-IR transmission was not a realistic possibility for monitoring this suspension of solid particles.

In the analysis of styrene to syndiotactic polystyrene on suspended particles, there is a particle size range which allows Raman spectroscopy to be used quantitatively to determine the concentration of liquid styrene dispersed on the surface of the polymer particles. For this particle size range, the Raman signal from the liquid monomer coating relative to that from the underlying solid polymer particles is linear over the operating range of the production reactor. The analytical results are based on measurement of the C=C stretching band at roughly 1640 cm\(^{-1}\), which is present only in the styrene monomer, relative to the 1000 cm\(^{-1}\) band due to the aromatic ring breathing mode, which is present in both the monomer and polymer spectra. Representative spectra from this on-line application are shown in Figure 5. These bands are sufficiently resolved to allow a rugged calibration based on peak areas of the bands of interest. In addition to the styrene monomer and polymer concentrations, concentrations of comonomers and copolymers can be determined as well. This process Raman analyzer was successful in achieving the desired results, providing fast analysis (less than 5 min) and good precision (±0.2% relative concentration) for the monomer. Moreover the probe exhibited no fouling in a period of over 1 year of operation and no analyzer drift was observed. The on-line analysis allowed the plant to operate with reduced contamination and labor costs than experienced with grab sampling.

5 SUMMARY

This article demonstrates the type of applications to which fiber optic Raman spectroscopy has been applied for process control. The number of potential applications for Raman spectroscopy in process control applications is really boundless. Because of the backscatter geometry employed in Raman spectroscopy, virtually any type of sample can be analyzed. Thus applications such as polymer fiber orientation, film morphology measurements, polymer crystallinity determinations, and pharmaceutical polymorph concentrations can all be performed on-line just as the more conventional chemical determinations of copolymer and comonomer concentrations. If the measurement or determination has been performed using Raman spectroscopy in the laboratory, the measurement can potentially be performed on-line as well. Many of these types of applications have been developed but cannot be reported for reasons of business propriety. The technological developments of recent years have transformed Raman spectroscopy from an underutilized technique of last resort to a technique of comparable value and versatility to its more universally accepted counterpart, IR spectroscopy. The instrumentation is significantly more rugged than in the early 1990s and is still changing rapidly. Raman analyzers in standard class I Division II instrument housings are now standard.
off-the-shelf units. Multiplexing several probes to the same instrument is now routinely offered as an option and rugged air-cooled solid-state lasers that operate efficiently at relatively low current (≤15 A) are standard and relatively long-lived. The large step-changes that have occurred since the late 1980s in laser technology, CCD technology, and spectrograph/filter technology have allowed this type of analyzer to be built. The advances which need to be realized now are the development of manufacturing practices which result in lower-cost instruments and components.

Unlike earlier revolutions in Raman spectroscopy, this current revolution in fiber optic dispersive Raman spectroscopy has demonstrated significant impact, well beyond the analytical laboratory and within the manufacturing process itself. The technology is still improving and it is likely that the desirability of Raman spectroscopy as an on-line analytical tool will continue to increase in the foreseeable future.

The purpose of this article is to introduce the reader to the important design characteristics of sampling and sample preparation systems for process analytical measurements, as well as to discuss several of the most commonly used configurations for gas- and liquid-phase process streams. Design criteria essential to the success of any process analyzer installation are discussed at length, and the pitfalls associated with neglecting these items are highlighted. This article provides an overview of what must be considered when building the interface between the analytical instrument and the process stream. It is not intended to be a comprehensive dissertation on the subject or a tutorial. The reader is referred to literature references and textbooks for detailed explanations and relevant design formulae. In addition, we also provide several sections regarding calibration procedures, maintenance concerns, and safety considerations.

1 INTRODUCTION

1.1 Objectives
It is our intention to give the reader an introduction to sampling theory and application for process analysis. Industrial process control depends more on analytical measurements than ever before, and, in order to obtain a maximum value for any analytical effort, the entire analyzer package must give an accurate picture of what is happening in the process. Although there are many well-built, robust analyzers on the market today, the interface between the process and the analytical instrumentation is often neglected and gives rise to most of the dissatisfaction felt by users. This interface, comprising the sampling and conditioning systems, requires attention throughout the conception, design, implementation, and maintenance phases of the process analyzer project. Generally, the requirements for a process that operates near steady state (continuously) are similar to those for a single-run (batch) process, but we will endeavor to differentiate specific needs where appropriate.

1.2 Scope of Article
This article focuses on the theory behind sampling, as well as the major sampling and sample conditioning
or preparation techniques used in process analytical chemistry applications. Whenever possible, the reader will be referred to more complete discussions on sampling topics, or to specialized sampling topics outside the scope of this work. For a more comprehensive treatment of the subject, the reader is referred to Carr-Brion and Clarke or to Houser. Additional information may be found in a number of sources specific to process analyzers.

1.3 Limits of Article

It is impossible to give the reader a comprehensive understanding of sampling systems and sample preparation in an article of this size. This article is intended to be more of an overview of the current state of the practiced art rather than a treatise on how to design, build, and maintain complex sampling systems. For detailed explanations or analyzer-specific information, please refer to the cited references. Although much effort has been expended in developing in vivo sampling systems, these are very specialized systems and as such will not be discussed here.

2 SAMPLING THEORY AND STATISTICS

In order to understand the purpose and function of sampling systems, it is important to review a few statistical concepts. A statistical representation or sampling of the process means that the aliquot of the process stream withdrawn from the bulk matrix will have component species in proportions matching the process stream. In the case of truly representative samples, replicate withdrawals of material from the process stream will all yield the same analytical results (within the statistical variation of the sampling system and instrumentation). As will be pointed out many times in this article, the overall variation in the analytical results is the sum of the variances from the process, sample withdrawal, sample conditioning system, and the process analyzer, collectively known as the measurement system. A block diagram of the measurement system is depicted in Figure 1.

2.1 Process Variability

The primary goal of any sampling system is to capture a representative portion of the process stream for presentation to an analyzer. Frequently, this goal is at odds with conditioning this portion of the process stream and placing it in a suitable form for analysis. Ideally, proportions of species in the captured sample should be identical statistically to the entire process stream at the sampling point. From a practical standpoint this may be neither necessary nor desired – it may be important to exclude portions of the process stream, such as particles or entrained air, prior to introducing the sample into an analyzer.

By conventional definition, a process that is in statistical control is within three standard deviations of the mean indicating variables. In normally distributed processes, 99.7% of all values will fall within these limits. For process analyzers this means that the measured species or properties in the process stream do not vary by more than three standard deviations within that phase of the process. A more detailed description of statistical control is given in section 7.

The process variability is typically the very reason for having a sampling system. Great care and attention must be paid to the range of this variation and the heterogeneity of the process itself. There could be particle size, solvent, pressure, temperature, or flow variations, which may give rise to heterogeneity in the process stream. Heavier particles, for example, tend to flow along the bottom portions of process piping. Filtration can remove solid particles and maintain the integrity of the gaseous or liquid phases in the process stream. However, if the solid portion needs to be included in the analysis (or worse yet, is the key part of the analysis), such as in detecting particle size or in measuring emissions from smokestacks, disregarding this information would be critical.

The ultimate goal of any sampling system is to provide a statistically representative sample to the process analyzer without introducing any variation from the sampling or conditioning processes. In this manner, the analyzer will respond strictly to the process variation.

Many types of process streams can be sampled. The more heterogeneous the stream, the greater the effort that must be placed in the design and operation.
of a sample capturing and conditioning system. The American Society for Testing and Materials (ASTM) has published a standard describing the practical and statistical considerations necessary for sampling industrial chemicals.\(^{13}\) As already mentioned, streams containing multiple phases may be sampled for process monitoring purposes. Nearly any stream can be sampled, provided that some motive force is available or can be added to extract an aliquot of the bulk material. Additionally, it must be possible to transfer this sample without altering the distribution of species in the sample or changing any of its key properties. This is sometimes quite difficult because the sample frequently continues to react after the sample is processed, and there is no way of quenching such a reaction without altering the components of the sample. In cases such as these, where true sampling is not possible, it is typically better to correlate the analytical results from the treated sample to the true conditions of the process stream.

Before determination of the sampling and analyzing methodologies, it is very important to consider how fast the process changes, and whether there is a pattern to this variation. For example, consider a wastewater stream flowing into a bioremediation vessel.\(^{14,15}\) Periodically, this wastewater may contain a few litres of highly concentrated solvent that, in a flowing stream, passes a probe for a total of 30 s. A sampling and analysis cycle of 2 min would have a low chance to detect such an upset. If the amount of solvent reaching the wastewater treatment is not sufficient to cause any problems, then concerns are negligible. However, if this amount of solvent causes a major kill of the microorganisms in the pond, the analyzer system would have failed to perform its basic function – to protect the bioremediation pond.

If, on the other hand, sampling occurs far more frequently than the process could ever change, the sampling system is said to be inefficient. Oversampling is not necessarily a poor practice – it becomes so when the effort required to maintain such a system is too great to justify the sampling rate. Sampling should generally occur at a rate sufficient to detect normal rhythmic changes as well as significant upsets in the process stream. From this point of view the sampling must occur at a rate sufficient to detect representative changes in the process stream.

In all cases, it is important to learn as much as possible about the random process variation, as well as the characteristic timescales and magnitudes of process changes that you wish to detect. It is then possible to match the analysis cycle to the process.

### 2.2 Sample Size Determination

In determining the appropriate sample size, a designer of such systems should always ask two questions: what is the minimum sample that will be representative of the process stream? and what is the minimum sample required by the analyzer portion of the system?

If the process stream, when partitioned to any degree, yields a sample with the exact proportions of the parent stream, the stream content is homogeneous. Any impure material cannot be perfectly homogeneous; that is, if a single molecule could be sampled in such a system, it would not be representative of the whole. Therefore, care must be taken to ensure that the sample is large enough and repeatable enough to represent the entire process stream (on a statistical basis). Many systems are heterogeneous and multiple samples of material from these systems reveal proportional nonrepresentation of the process stream. In order to test whether a stream is homogeneous or heterogeneous, statistical analysis of repetitive samples is typically required.\(^{11,12,16}\) If the spread of analysis is either nonrandomly distributed or is greater than the expected level within the measurement system (analyzer and operator), we suspect heterogeneity.

Capturing the process variation may be accomplished by taking multiple samples separated temporally or spatially. These may then be analyzed as replicates or as a composite sample. In either case, a more representative picture of the process stream may be developed. Caution should be exercised when drawing conclusions from composite samples, because the true process variation may be averaged out in such samples.

Operator, analyzer, and sampling system constitute the measurement system. The instrument system performs best when the sample stream is effectively homogeneous (the degree of heterogeneity does not contribute a statistically significant error to the measurement system), or when the sampling system provides a true, statistically-valid sample for the analyzer.

If done properly, sample conditioning (filtration, phase separation, heating, cooling, etc.) will not affect the required analysis. Any significant changes in the sample effected by the conditioning system must be scrutinized closely to ensure that the important characteristics of the process sample remain unchanged.

### 2.3 Sampling Frequency

How often a sample is withdrawn from a process stream defines the sampling frequency. This concept, although straightforward, is often overlooked in the design phase of the instrument system. Commonly, designers will spend a great deal of time and money to place a system in operation that will produce analyses every few seconds, only to discover later that the process is slow to change and the designer would have been better served to maximize the accuracy and precision.
It is always a trade-off between how often we must sample and how much time and effort we are willing to put forth. The bottom line is that we must sample at the frequency appropriate to capture the process stream variation, no matter what the cost, otherwise the analyzer will not provide useful data and will not be successful.

As indicated earlier, one must consider the rate of process change before recommending a measurement system. In order to control any process, feedback must occur on a timescale that is faster than the rate of change within the process stream. This is intuitive; process upsets must be captured within sufficient time to effect a change. Ideally, one must be able to know that an upset has or is about to occur—plant operators have differing opinions on exactly what constitutes knowledge in these cases. With today’s analyzers, it is usually possible to sample, condition, and analyze fast enough to give the operator ample warning of the imminence or the beginning of a process upset.

In order to control any process, the analysis must give feedback within a shorter timescale than that in which significant changes are likely to occur. Many operators will not take action until two indications are received to suggest that a process is out of control, or at least progressing toward an out-of-control condition. The response required for batch operations is typically different than that for continuous processes. In the continuous process, species or properties being measured could be related to the final product, to a key control parameter such as pH, or to an impurity in the system. In a batch process, the moiety of interest is commonly that item whose target value specifies the product, or the intermediate material prior to the next production step.

Most sampling systems are continuous in nature; that is, the sample stream or some portion of the process stream is constantly passing through the plumbing that comprises the sampling system. It therefore follows that the sampling system is typically not the slowest portion of the measurement system. If designed correctly, the sampling portion of the instrument system will present to the analyzer a sample with minimal age, or the freshest sample possible. After a portion of the process stream has been removed and placed within the sampling system, changes in temperature, flow, materials of construction, and time itself can cause changes in a representative sample. This is the reason why we wish to minimize the time lags between extracting, conditioning, and analyzing a sample. When a single analyzer is measuring multiple streams, this consideration becomes even more important. Not only must a multiple-point sampling system deliver fresh sample, but it also must prevent cross-contamination between the streams.

When installing a single analyzer for multiple process stream monitoring, one must consider (in addition to the cross-contamination possibilities) the effects that multiplexing will have on the response time. Even when the sample transport system is carefully designed and extremely responsive, overloading a single analytical instrument can have catastrophic effects on its performance.

2.4 Sources of Error

There are many potential sources of error in the sampling portion of any measurement system. Errors may originate from the transfer of sample from the process stream to the container or line outside of the stream, from the transport of the sample to the laboratory or process analyzer, or from the transfer from the container or sample line into the analyzer.\(^{17,18}\)

When capturing a process sample, the first question to ask is: what are the requirements of the sample? If a sample is to be wholly representative of the process at the sampling point, it must include all the species present in proportions matching the process. If one is interested in only gaseous or liquid components, not only must all other phases be excluded but the sample transfer must not be impeded by the presence of other phases. The sample probes—those devices that accommodate the transfer from the process pipe—must also be designed so that any undesired discrimination does not occur.

When transporting the sample in either a detachable container or through a sample line, leaks into or out of the vessel may occur. One may accept a small amount of leakage if neither partitioning of the sample nor safety or environmental concerns arise. It is rare that both conditions would be met.

Sampling systems fail for many reasons, including hardware failure, improper design, or incompatibility with either the process stream or the analyzer. Components such as filters, valves, and connectors may plug. This may be true especially if there are problems in maintaining the pressure, temperature or flow of the process stream. Every effort will be made to point out where such faults may occur in the specific sections that follow.

Even in cases where the sampling process has been minimized, there may still be problems. In the case of surface-sensitive techniques (e.g. attenuated total reflectance spectroscopy), the physical characteristics of the process fluid, such as miscibility or surface tension, may cause segregation of the sample at the probe. Also, key process variables, such as temperature and pressure, must be addressed to ensure that changing them will not adversely affect the sample. If possible, maintain the sample condition as closely as possible to the process conditions.
3 GENERAL CONSIDERATIONS

3.1 Sampling System Criteria
Along with being representative of the process parameter being investigated, the criteria of the sampling system are the deliverable commodities of the sampling system.\(^{(4)}\)

When designing a sampling system, these features should always be considered.

3.1.1 Robust
A robust system withstands not only the rigors of the process stream but also the rigors of the environment in which the system is installed. The system must function as intended over a reasonable period of time without the need for excessive maintenance. Both the “reasonable period of time” and the “excessive maintenance” are user-defined performances. Users will often invest a great deal of effort into maintaining a sampling system and instrument system that provides crucial process information. Of course, the ancillary consideration is also true; if an instrument system provides unimportant or inaccurate insight into the process, very little, if any, maintenance would seem reasonable.

3.1.2 Reproducible
Ideally, a reproducible sampling system is one that, when presented with identical samples, will yield identical results. Practically, such a system will persistently indicate the properties or species of interest under normally varying conditions. The reproducibility is a measure of the overall system precision, not that strictly of the analysis portion of the scheme. One would like the sample transport and conditioning to have little, if any, effect on the variation in the analytical results.

3.1.3 Timely
Any sample pulled from a process stream is a measure of the stream at that point in time. It is a snapshot of what has occurred, not of what is occurring. This realization is very important because users need to understand that, except for direct-responding in situ probes, all samples have an age associated with them. It should be the goal of the sampling system designer to make the capture and analysis of a process sample fast enough to detect deleterious events before problems arise. In the case of sampling for laboratory analysis, not only does the sampling system need to reflect accurately the process stream at that point in time, but also the sampling plan needs to consider how fast the process stream changes.\(^{(13)}\)

3.1.4 Economical
Sampling systems often cost as much or more than the analyzers they provide streams for. The service they provide should not be minimized, but wherever possible this service should be economized. The elegant approach is usually the best – the designer should construct a system that is easy to follow and maintain. Additionally, thought needs to be given to whether a sampling system may be shared by an analyzer, or an analyzer shared by multiple sample streams, without harming the performance of any one unit.

3.1.5 Safe
The sampling system resulting from the design effort should be as safe as the process piping to which the stream connects. Caution should be exercised when the materials transported by the system are under pressure, contain corrosive or erosive materials, are flammable, explosive, or reactive, or may cause an unsafe condition to exist when removed from the process piping.

3.1.6 Maintainable
Any components of the sampling system that require routine maintenance or repair should be designed in such a way that there are alternate flow paths and proper clean-out facilities. Having to completely shut down a process to replace a filter is not a desirable design characteristic of any sampling system.

3.2 Transport Time Requirement
When moving a sample from a process stream, there are a number of objectives that need to be addressed. The first is the time lag that the user can afford; this depends largely upon how fast the process changes.\(^{(19,20)}\) Next, remembering that the analyzer cycle time is additive to the sampling system lag time, what is the total delay time in the system? Can we live with this total cycle time? The motive force for moving the sample throughout the system then needs to be considered. What equipment such as pumps and gravity feeders exists? Finally, one should consider the phase of the sample. What is the phase in the process? What phase must the sample be in for the analyzer?

A number of strategies exist for moving samples through a system. These include using an in-line probe for direct analysis within the process stream, vaporizing samples from a high-pressure tap for vapor transfer to an analyzer, using added or existing pumps to make a slipstream, and using the pressure differential between the suction and discharge sides of the pump.

If the measurement technique is well suited for direct measurement within the process stream, and if the process stream conditions are not too rigorous for the probes associated with these techniques, in-line measurement may provide the most timely and
representative analyses.\textsuperscript{15,21} The two main methods for installing in situ probes are: a single-point investigation of the process; or transmitting energy through the process stream from an excitation probe to a collector probe.\textsuperscript{21–26} Optical probes for visible and near-infrared spectroscopic measurements may be mounted in the process stream, with the excitation and response signals transmitted back to a spectrometer using fiber-optic cables. Infrared spectroscopy has been performed in a similar manner with the light being transmitted through an inert gas-filled light pipe. Optical probes may be used in either single-point- or transmission-type modes. Potentiometric probes, such as those for measuring pH or ionic species, are single-point measurements that will measure directly in the process stream – if favorable conditions exist.\textsuperscript{13–5} The drawback for measuring process streams in line is that very few process streams will not foul or coat these probes. Additionally, these measurement techniques may not be appropriate for the analyses required by the user. Finally, either any probe mounted directly into the process stream must be removable for replacement or maintenance, or the entire process must be stopped and the stream declared safe for maintenance to occur. Alternate flow paths allow for maintenance and repair without requiring a complete shutdown of the process. If possible, redundant instruments or analyzers will provide backup capability in case the primary unit goes down for any reason.

3.2.1 Vaporization

Direct vaporization at a sample tap may be the best approach if the process monitor requires a gaseous sample for analysis.\textsuperscript{2,27,28} In most cases, the pressure is dropped through a heated regulator that volatilizes any liquid materials. The heated regulator is also used to prevent droplet formation in vapor sample streams due to the Joule–Thompson effect. This technique is commonly used when pumps or compressors are not readily available and when the gaseous sample does not need to be returned to the process stream.

3.2.2 Slipstream

The slipstream technique is probably the most common sampling technique for process analyzers and laboratory analysis. Figure 2 illustrates a “fast-loop” configuration of the slipstream technique. In this method, a process pump at the point of interest is used to move the sample to and from the process monitor. A small stream is taken off the pressure side of the pump, transported through the sampling system to the process analyzer or sample container, and returned back to the process stream through a small inlet on the suction side of the same pump. The pressure differential between the suction and discharge sides of the pump provides a strong force to move the sample through the system.\textsuperscript{1–5,29,30} The amount of material being recycled back to the process is designed to be sufficiently small to be negligible. As shown in the diagram, two three-way valves may be used to block the sampling system from the process stream, as well as to purge or clean the sample lines.

3.3 Materials of Construction

After function, the next most important criterion when building or designing a sampling system should be the materials of construction. The sampling system itself must be compatible with the process stream constituents as well as the temperatures, flows, and pressures of that stream. A sampling system designer must look at all the components that comprise the measurement system to see whether any opportunity exists for failure due to material incompatibility. Flowmeters may contain O-rings that swell in the presence of certain organic solvents. Valves may contain soft plastic seals that wear quickly in a stream containing hard particulates. Every effort must be made to investigate all potential failure modes of components to ensure the greatest reliability possible of sampling systems. In addition to Perry’s Chemical Engineer’s Handbook,\textsuperscript{31} there are a number of good sources for defining and investigating material compatibility issues.\textsuperscript{32,33}
3.3.1 Corrosive Systems

Some process streams are obviously corrosive, such as those in plants that produce highly corrosive materials such as chlorin or hydrofluoric acid. Other processes may use corrosive materials such as sulfuric acid, and others may produce corrosive materials as byproducts. Some streams, such as phosgene, are not corrosive under dry conditions but as little as 20 ppm of moisture will produce highly corrosive species, such as hydrochloric acid, which may also cause serious safety concerns.

3.3.2 Organic Systems

Whenever organic systems are monitored using either a sampling device or an entire sampling system, not only must one consider possible sources of corrosion but also possible sources of dissolution, swelling, and other interactions due to the solvating power of the process stream constituents. A practical approach would be to list all components that may contain elastomeric materials, such as valves, regulators, and pumps. Next, review the process stream constituents along with the extremes of temperature and pressure. Finally, make certain that all wetted parts are compatible with the process stream mixture or specify alternative materials that are compatible. Identify any unknown material interactions as initial points to check during early maintenance checks.

3.3.3 Inertness

A common misconception is that certain materials such as Teflon® or stainless steel are inert. For many analyses these materials are effectively inert, i.e. these materials do not interfere with the analysis being performed to a measurable degree. Teflon® is known to convey gases such as oxygen and to entrap certain materials such as methylene chloride and hydrofluoric acid. If percentage-level measurements are being performed, the interaction level is probably negligible. If, however, one is performing parts-per-million-level measurements, these interactions may be the cause of great uncertainty in the measurement system. Water will similarly adhere to metal surfaces. This is not ordinarily a problem, but when measuring very low levels in a water-sensitive process the measurement system will be slow to react to changes because of adsorption and desorption phenomena.

4 SAMPLING OF FLUIDS

Many of the concerns of designing sampling systems for liquids are the same as those used for gases. Sampling systems for liquids use many of the same components as those for gases, and the performance criteria are generally the same.

4.1 Design Considerations

Simplifying the measurement system should always be a primary objective of any designer of sampling systems. When moving fluids through a sampling train, one must realize that every added component affects the response time of the measurement system. Filters, valves, and even fittings can cause restrictions that slow the flow of fluid through the sample transport system, which, in turn, slows the overall response time. The sampling point also is often overlooked by sampling system designers. As pipe diameter decreases, laminar flow becomes more of a concern. Laminar flow approximates to plug flow, which means that poor mixing occurs in the stream. When mixing is poor, there is little opportunity to capture a sample that is representative of the entire process.

The main criteria associated with all sampling schemes apply especially to fluids. Any captured sample must be representative, i.e. changes in any process moieties must have corresponding changes that are directly related in the portion extracted from the stream. Note that the concept of accuracy is not raised here. It is often far more important to detect changes in the process stream than to know exactly what the concentrations of those species are. To be certain, accuracy is an important function of any measurement system. However, depending on the nature of the measurement, and the process point being measured, a degree of accuracy may be sacrificed in favor of repeatability.

Repeatability refers to a measurement system’s tendency to yield the same value when presented with the same sample. If the measurement system has a high degree of repeatability, changes in the process are easy to detect. If a system has good accuracy but poor reproducibility, control limits will be fairly large, meaning that small but important process changes are more difficult to detect.

4.1.1 Analyzer Requirements

There are many different types of analyzers that may be mated to process streams via sampling systems. These analyzers, which range from chromatographs to spectrometers, from pH sensors to moisture analyzers, and from turbidimeters to refractometers, may have different requirements for accepting a flowing stream. In some cases, the sampling system needs to drop the temperature, pressure, or flow of the stream before it is introduced to the analyzer. In other cases, extensive filtering or coalescing may be required within the sampling train. In still other cases, the phase of the sample may need
4.1.2 Phase Considerations

The simplest type of sampling occurs when the process stream is at near-ambient conditions of pressure and temperature and contains a safe, dry, clean stream. Unfortunately, few, if any, streams approach the ideal case. To further complicate matters, many streams contain multiple phases. One can envisage a cross-section of a pipe in a corrosive, hot process where the process stream is liquid, but at the bottom of the pipe are solid rust particles and at the top of the pipe are gas bubbles (perhaps dissolved air that after a pressure drop or temperature increase was no longer soluble in the liquid). In order to picture what is happening in the process stream, it is advantageous to exclude these nonparticipating species, unless we are specifically interested in the degree of corrosion or oxygen or moisture content. When faced with such a situation, there are a number of design considerations to explore. Is this the best sampling point? Can these other materials easily be excluded from the sample train without complicating the measurement system? How does the decision made affect the repeatability and representative nature of the sampling system?

4.1.3 Maintenance

The maintenance of the sampling system is often overlooked when designing the installation of a process analyzer system. Frequently, however, the components that comprise the sampling system often require more maintaining effort than the analyzer portion. It is here that the line sizes, filter sizes, valves, regulators, and flow indicators must be considered carefully. Often there is a trade-off between ease of design, ease of installation, cost, and maintainability when designing and constructing a sampling system. Functionality is not a negotiable factor and, hence, is the design foundation of any sampling system. High regard should be placed on the maintainability of the system – if the system cannot easily be maintained, it will not be made use of unless the measurement afforded by the system is of extreme value.

4.1.4 Multistream Sampling

The plumbing system used to monitor multiple streams is known as either a multipoint or multistream sampling system. It is common practice to install a single analyzer to monitor multiple streams in processing plants for a number of reasons. The primary reason has been cost, where a number of very similar streams that require process analysis are in close proximity to one another. Under these conditions it may be possible to leverage the cost of a process analyzer by providing an analysis of all of these streams. Another important justification for using multistream sampling systems is the availability of space – a plant may not have the ground space to accommodate multiple gas chromatographs, for instance. Other considerations include safety, maintenance of a single analyzer, and modifications to existing systems. When designing a multipoint sampling system, there are additional requirements that need to be considered:

- response time from individual streams;
- manifold size and function;
- contamination from previous sample during the analysis (often called cross-talk);

![Figure 3](image-url) A version of a block and bleed set-up for multistream sampling. Closed ports are shown as blacked-out paths. Flow proceeds through valves 1 and 3 into the analyzer; excess pressure is vented through valve 2 and a restrictor.
contamination from one stream into another; and

synchronization of analysis events.

The most common valve configuration for multipoint sampling systems is the block and bleed approach shown in Figure 3. Although only two sampling points are illustrated here, the points may be duplicated many times over. This technique stops the flow of all nonselected streams from entering the analyzer and vents any sample between the blocked valve and the instrument to atmosphere or to the low-pressure return line. There is always one stream active but the remaining streams are blocked using this method. The valves are synchronized by connecting the pairs to the same pneumatic or electric actuators – this also prevents cross-talk to a large extent.

A better approach is the double block and bleed method, which has additional valve components that trap components from a previous stream behind two valves. The flow diagram of this technique is shown in Figure 4. The use of the second three-way valve allows the fluid remaining in the tubing to be cut off fully from the analysis train. Both valves are normally vented to atmosphere or an otherwise low-pressure stream, preventing pressure leakage past the valve.

The two other major techniques for multipoint sampling of fluids are backflushing and bypassing. In the backflush technique, the active stream, when selected, not only passes into the analyzer but also backward through the nonselected stream to an orifice just prior to the selection valve. The orifice connects to a low-pressure vent, such that the selected stream will flush out residual sample from the previous stream. In the bypassing technique, the nonselected streams flow continuously through the normally open port of a three-way valve. This prevents pressure from building at the valve itself. With the bypass principle, the pressure of the selected stream should always be much greater than the bypassed streams, preventing contamination. The bypass configuration also ensures fresh sample from the process, because the nonselected streams always flow from the sample tap. Neither the backflush nor bypass sampling system is generally used widely by itself. The double block and bleed system is commonly configured with bypass lines, especially when the discarded sample is recycled back to the process stream. All these methods may be used with a sample bomb or capturing device in place of the analyzer. The sample stream sweeps through the bomb, forcing out old sample or air with fresh sample.

4.2 Sampling Modes

There are basically two ways to make measurements for process streams: in the process stream itself or by extracting a sample from the stream. Laboratory analyses are of course extractive by nature in that a portion of the process stream is removed from the process and brought to an analyzer housed away from the process. A true in-line analyzer or probe is placed in the process kettle or flowing stream. On-line analyses can either be in-line or extractive. Some techniques obviously require one mode, e.g. all chromatographs use extractive sampling. In other cases, such as monitoring spectroscopic properties, one can use an in-line measurement or could extract sample in order to condition the stream for the analysis.

4.2.1 In-line

These types of analyses either are performed directly within the process stream or use a probe that looks directly into the process. Direct analysis probes such as those for pH, oxygen, and water are generally self-contained, except for power and signal umbilicals that bring in electricity and transmit readings. These probes are usually

![Figure 4](image-url)
mounted through a tee mated to the process line. Probes for spectroscopic analyzers such as refractometers or infrared photometers either may be mated to the process stream via a tee or will be built around the process pipe such that energy transmits across the stream.

The requirements for tee-mounted devices are generally the same regardless of the analytical technique employed. Single-point devices require that fresh sample comes in contact with the probe surface. The designer therefore needs to be certain that these probes are inserted into portions of the stream with turbulent flow, avoiding areas where plugging or dead space may occur. Because some spectroscopic instruments transmit energy through the bulk stream during the measurement phase, these instruments require that the portion of the process stream in the light path be representative of the process.

In either case, the most troublesome problem for inline devices is fouling or coating of the active surface. With electrochemical probes, such as those for moisture or pH, fouling results in inaccurate results by prohibiting a representative portion of the process mixture from coming in contact with the sensing surface of the probe. For many transmission instruments, fouling may cause absorption of the transmitted energy, causing baseline shifts, inaccurate results and heavy maintenance. A number of methods have been used to mitigate or eliminate fouling. Occasionally, simply by choice of materials, fouling may be avoided. In other cases, a water, steam, or solvent flush is programmed into the analytical cycle to clean the sensor surface periodically. Additionally, one may raise the temperature or stream flow rate in order to prevent materials from adhering to the active surface of the probe. Some of the spectroscopic probes utilize ultrasonic cleaners for continual refreshing of the optical surfaces. Finally, maintenance can be performed preventatively, before the fouling is significant.

4.2.2 Open-path or Ambient
Direct measurement of chemical species in the atmosphere is a specialized case of in situ monitoring. Open-path monitoring involves measurement of gas-phase compounds by absorption spectroscopy realized between a light source and a detector spaced far apart. This technique is gaining in popularity for fugitive and stack gas emission detection. The most common open-path techniques make use of the power of Fourier transform infrared (FTIR) spectroscopy. The special efforts to be taken when sampling ambient air are thoroughly described in an ASTM standard.

4.2.3 Extractive to Waste
As mentioned previously, process sampling for laboratory analysis requires the extraction of a sample that will rarely, if ever, be returned to the process stream. There are many devices used to capture a representative sample for subsequent analysis by a laboratory instrument. The major considerations for process analysis by a laboratory instrument are:

- timescale of analysis;
- response time required by plant operations;
- stability of the sample; and
- laboratory analyzer’s requirements of the condition of the sample.

A sampling system designed for capturing a representative sample for transport to a laboratory has more demands placed on it than does the supply system for a similar on-line analyzer. By virtue of transporting a sample to a laboratory, these sampling systems must have a removable container that integrates into both the process and laboratory sides of the measurement system.

Some process analyzer systems also send all captive sample to a waste (or vent) stream. It is common in these systems to run a fast bypass loop near the analyzer while removing a portion for passage through the analyzer to a waste stream. This keeps the response time low while minimizing the process stream waste. This may be necessitated by the type of analysis, such as a gas chromatograph requiring that a liquid stream be vaporized continuously before filling a sample loop. More commonly, some processes, such as those in the food and pharmaceutical industry, require that no contamination occurs, and this technique is absolutely essential.

4.2.4 Extractive to Return
This is the most common sampling methodology for process analyzers to utilize. In this technique, a portion of the process stream is brought out of the main flow path through an analyzer and returned back to the process. This smaller, recycling, flow loop is usually referred to as a slipstream. Typically, the designer of the sampling system uses a pressure differential already existing within the plant as the motive force to move the portion of the process stream through the analyzer. For example, the inlet to the sampling system can be from the discharge (high-pressure) side of a process pump, and the sample is then returned to the suction (low-pressure) side of the pump. The sampling system designer first considers the pressure across the pump, then determines the flow needed for a satisfactory response time, and finally calculates the tubing and associated pressure drop of the sampling system. If the process does not contain sufficient motive force to supply the sampling system, additional hardware such as pumps or aspirators might need to be added to the sampling system. A complete discussion of
the calculation of pressure drop in a sampling system is given by Sherman and Rhodes.\(^4\)

### 4.3 Sampling Point Determination

Determining the best sampling point for process analysis requires the designer to consider not only the process but also the process stream. The sampling system needs to be compatible with the process stream at the sample tap. The sampling point must also be meaningful from a control viewpoint. Finally, the sampling point and related hardware must also be maintainable. Often, the sampling point chosen for process analysis is a compromise among all considerations.

One other consideration is the integration of an extractive sampling point for laboratory analysis. Samples will have to be pulled occasionally for validation of the on-line analyzer. Building in a laboratory sampling point at the same location in the process makes sense in terms of direct comparability of the results.

Ideally, the best sampling point will yield the most information about the process stream. It will give a representative view of the production in a timely fashion, allowing experienced personnel to adjust key parameters before any upsets occur. This is a critical consideration – one must have the control requirements of the analysis closely aligned with the sampling point for the measurement system. Failure to marry these two concepts could lead to a failure of the installation to provide useful information. The sampling system designer must choose the sampling point carefully – he or she must select the tap and allow for transport and analysis time when calculating the response time of the measurement system.

Often the sample tap that would yield the best response time is not the best point for producing either a maintenance-free system or a representative sample. In these instances, a compromise must be made between what is expected and what is practical. Often, after a pressure drop in a gaseous flow the stream is more homogeneous due to turbulence at the restrictor. Although the high-pressure side would produce faster flow in a slipstream, the better choice may be to tap into the low-pressure side to catch a more representative sample.\(^{30,39–41}\) This would be especially true if there still were enough pressure to move the sample quickly to the analyzer, or if an auxiliary device such as a pump could be added easily to the sampling system to augment the flow.

Sample stability in the transfer line leading to the analyzer or sample vessel is of great importance. Changes in flow, pressure, and temperature could lead to partitioning of the sample matrix, which causes the captured portion to lose its representative nature. A hot gas, for instance, could adsorb to the walls of cooler tubing; this adsorption leads to a memory effect. Adsorption of materials will cause species not to be detected as quickly as the flow would indicate, whereas desorption of these species into an otherwise “clean” sample stream would cause the analyzer to register values after the process stream was clear.

### 4.4 Sample Transfer

The response time of any process measurement system relies on the time it takes to transfer a sample from the process stream to the analysis device. In some cases, the measurement time is fairly long, such as in gas chromatography, where 10-min cycle times are typical. In other cases the instrument response time is negligible, of the order of seconds. It is in the latter case where sample transfer is typically the limiting portion of system response time. The two main design considerations of sample transfer are the linear velocity (speed) of the sample and the amount of plumbing (distance) to the analyzer through which the sample must travel.

Speed of response for process measurement systems can be achieved by either placing the analyzer close to the sampling point or allowing the sample to flow quickly from the tap to the analyzer. The electrical classification of the area near the sampling point as well as the available space often limit how close the analyzer may be placed to the process. In those cases where sample flow is not a problem, it is often best to locate the analyzer in a safe, convenient location and use a fast-loop bypass to waste or to a plant return. Obviously, if there are pollution or cost issues, it is best to return the sample back to a lower-pressure point in the process stream. The extractive-to-return system can be configured with a bypass that is always flowing at a high flow rate while a small portion of the sampling stream is sent to the analyzer or sample-capturing portion of the sampling system. This design ensures small lag times and can accommodate small-volume analyzers. It is important to note that the return points in fast-loop systems must be considered carefully. Fast-loop sampling relies on differential pressure within a process and should never be placed across control valves for fear of adversely affecting control of the process.

The amount of sample to be transferred to a process analyzer is determined by two factors. First, what dimension of piping needs to be used to keep the pressure drop at an acceptable level? Second, what portion of the process stream must be transferred to the analyzer for accurate representation of the process? Typically, a designer will aim for at least three volume flushes of the sample transfer lines for either laboratory or discontinuous analyzer sampling. This rule of thumb is employed to be certain that the captured sample is representative of the process by washing out sample...
remaining in the lines from a previous analysis. For continuous analyzers, the constant flow through the pipe leads to a defined lag time for the entire measurement system.

Transfer lines and their associated hardware must be compatible with both the analyzer and the process stream and must be designed with the system requirements in mind. All components must be sized correctly to allow for the desired flow. The lines should be run in a linear fashion as much as is practical; bends and elbows slow response time due to axial mixing. Turns could also cause problems such as plugging or the formation of dead volumes. Wherever bends in the sample transfer lines are necessary, provisions should be made for cleaning and maintenance. Whenever possible, lines should be sloped to allow for proper drainage of condensable gases and to prevent particulates from settling.

The hardware also must be constructed of appropriate materials, and during the design process consideration of the process piping is used to determine these materials. Because of the smaller dimensions and analytical nature of these components, greater care needs to be taken. Corrosive and erosive processes are more severe with thin-walled sampling system tubing than they are with thick-walled process piping. In addition, adsorption is not a primary concern in process piping, but it would be in the stream leading to an analyzer. Finally, the valves and other components associated with the process stream are more resistant to plugging than their finer counterparts located in the sample transfer lines. An ASTM standard practice on flow and temperature control in process measurement systems discusses these concerns more completely.\(^{42}\)

4.5 Sample Conditioning

A primary function of any sampling system is to condition the sample for analysis. The sampling (sample conditioning) system is responsible for making the transition from what is in the process stream to what the analyzer is capable of accepting without changing the sample composition in a meaningful way. Sample conditioning can be as simple as adjusting temperature or pressure, or as complex as quenching a reaction or vaporization of a liquid stream. The degree of conditioning may depend upon the physical state extremes of the process, or upon the chemical nature of the sample itself. The amount of conditioning is also dependent upon the constraints of the analyzer system itself, such as the size and amount of particulates that may enter analyzer components. Finally, conditioning is dependent upon the performance criteria of the sampling system itself, such as easy maintenance, and avoiding corrosion and plugging of the sample lines.

4.5.1 Representative Nature

In a strict sense, sample conditioning tends to make fundamental changes to the sample. By removing particulates using a filter, constituents of the process stream have been preferentially removed, and the sample is no longer representative of what was in the process stream. This is acceptable if there is an understanding that the removed components are either not part of the process or can be accounted for via calibration or some other technique.

4.5.2 Liquid Vaporization

Sample conditioning includes vaporization of liquids to gases. This is done for one of three reasons: to reduce lag times; to keep portions of a gas stream from condensing; or to present a gas sample to an analyzer requiring such. If either a liquid or gas could be analyzed as part of a measurement system, the gaseous form is often preferred because less sample may be used and higher flow rates may be achieved. Often, sample lines may be heat traced above the dew point of any component in the process stream in order to prevent condensation, which leads to disproportionate moiety concentrations in the captured sample.\(^{43}\) Gas chromatographs may require vapor samples, depending upon the interface to the sampling system. By vaporizing samples as close as possible to the sampling tap, a fast-flowing representative sample is presented to the analyzer. Means used to vaporize samples include heating or insulating sample lines, steam-heating vaporization lines, and vaporizing regulators with electrical or steam-heating sources.

Another way to vaporize a portion of the sample stream is by stripping or sparging. In this technique, an inert gas is bubbled through a trapped portion of a liquid stream. The most volatile components travel with the inert gas to a gas analyzer whereas the spent liquid stream is sent to waste or back to the process stream. A similar technique is headspace analysis, where a portion of the liquid process stream is sent through a chamber. The liquid does not fill the chamber, instead volatile species travel to the headspace above the liquid and are subsequently sent to a gas analyzer using an inert gas. These techniques are good choices when the liquid streams are difficult to clean or contain high concentrations of dissolved solids. Both of these techniques require good control of flow rate and temperature to achieve reproducible analyses.

When considering process measurement systems, one needs to determine what phase the sample captured or presented to an analyzer will be in. Although in many cases either a liquid or gas may be used, one phase may be preferred over another. Gas chromatographs, because of maintenance associated with liquid injection valves, usually favor gas samples. Spectrometers, on the other hand, because of pathlength limitations, may favor
liquid samples. Other considerations include the ease of conditioning the sample further, the additional hardware required, and, most importantly, which phase maintains the sample integrity.

4.5.3 Temperature and Pressure

Both the sample temperature and pressure must be controlled in order to control the phase of the sample. It may be necessary to cool or heat the sample or to maintain or reduce its pressure as it travels to the analyzer portion of the measurement system. Bubble formation and disproportionation of the sample may be avoided by maintaining pressure or by cooling the sampling stream. Cooling may also be necessary if the process stream contains reactive species. The most common reasons to reduce pressure in a sampling system are to provide the analyzer portion with a low-pressure sample and to provide an easily manipulated sample stream.

An added benefit of reducing the sample pressure for analysis is safety. In the case where the sample is brought into an analyzer shelter or room, high-pressure sample lines are not desirable because of the possibility of oxygen displacement in the event of a leak.

4.5.4 Filtering and Separation

Because the goal of any sample conditioning system is to present the analyzer with a representative portion of the process stream ready for analysis, removal of particulates or other harmful species needs to be considered. As mentioned previously, removing entrained species is a preferred practice if these species are not of interest or cannot be accommodated. There are many separation techniques used in sampling systems; the method employed depends on the specific problem to be solved. Separation may be effected at the inlet to the sample transfer lines, within the lines, or at the outlet to the analyzer portion.

Particulates are removed from dry gases using filtering. Filter materials may be sintered metal or wire mesh made from appropriate materials. Filter elements may also be membranes, metal disk arrays or fiber tubes. Other materials such as ceramics and plastics have been used extensively; again, one must consider material compatibility with both the physical and chemical property extremes of the process. Self-cleaning filters, such as bypass filters, may be used in parallel to make a long-lasting, easily maintainable system.\(^{[34,44]}\) Placing the filters in parallel also allows for maintenance without shutting the system down.

Cyclone filters are also used to remove particles from gas and liquid streams. In such a device, the incoming sample fluid forms a vortex; centrifugal action forces the separation of particles and droplets. Gas bubbles caught in liquid streams are also readily removed using the cyclonic action. Although the smallest of particles are not removed using this equipment, pressure drops are often significantly less than those experienced in pass-through filters. Cyclonic filters are also easily incorporated into fast-loop sampling systems. The main drawbacks of these devices are that flow rates of sample and bypass streams need to be determined experimentally and then controlled.

Another device used to separate liquids from gases is a coalescing filter. Liquids are removed from gases by being trapped on a porous bed, accumulating and dropping out of the flowing stream or by being sent to the bypass stream. Bubbles may be separated from liquids using an inverted coalescing filter, allowing the vapor to travel up to the top of the device.

5 SAMPLING MIXED PHASES

Phase heterogeneity occurs in numerous production processes. Here heterogeneity is defined as having more than one phase present in the flow stream being monitored, rather than differences within very small samples being withdrawn from the stream. Heterogeneity exists either by design or by accident, such as when temperature or pressure upsets occur within a plant. Sampling such systems requires some process knowledge as to whether all phases are to be sampled and analyzed, or whether the sampling system must effect some type of segregation. In this section, emphasis is placed on incorporation of all process variability into the measurement system, i.e. sampling the bulk and obtaining sufficient representation of the entire process stream.

5.1 Classifications

Regardless of the nature of the nonuniformity of the sample, the sampling system designer must attempt to create random heterogeneity in the sample that is captured. The portion of the process stream captured must reflect the heterogeneity of the process as a whole.\(^{[45–48]}\) If the sample captured is biased in any fashion, the system must either be corrected or calibrated to account for the bias. In order to capture a representative sample, portions withdrawn from the process stream tend to be larger than those removed from homogeneous systems.

5.1.1 Gas–Liquid

Process streams consisting of a mixture of gases and liquids are typically not sampled for process control, often because this condition is not a normal mode of operation. Exceptions to this rule of thumb usually occur
due to temperature or pressure cycling, typically in batch vessels or occasionally in distillation systems.

5.1.2 Liquid–Liquid

Immiscible liquids, which in a static system would normally separate into two phases, can form emulsions in process streams. Emulsions are tiny droplets of a liquid (disperse phase) suspended in another liquid (dispersion medium). Some industrial processes are designed to use emulsions (such as block polymer additions to latex particles), whereas in other cases emulsions form due to process upsets (an organic liquid exceeding its saturation point in an aqueous mixture). When sampling such mixtures, it is typically important to maintain the emulsion as it is in the process stream, for fear of disproportionation occurring.

5.1.3 Solid–Fluid

Solids may be dispersed in either gas or liquid process streams. Smokestacks contain particulate matter suspended in flowing hot gases. Other processes may use fluidized beds or pneumatic transfer of solids. In each of these cases, sampling may need to capture both the solid and gas phases. In sampling such systems, one needs to be mindful of erosion and abrasion processes degrading the sample transfer lines and components. Process liquid streams may also contain solids by design or by lack of process control. Solubility loss can lead to solid particles precipitating from solution (which may be planned or unplanned). In other cases pastes, suspensions, or slurries may be formed to achieve process objectives.

5.2 Design Considerations

In all mixed-phase systems, the designer considers the rheological properties of the blended substances. Understanding how these materials flow often leads to how they are sampled. Solids in slurries, for instance may not settle in a static system, but when pumped they may exhibit segregation due to flow. Pastes also may flow and maintain representation of the process under certain conditions but, when heated or overly compressed, could lose this character.

5.2.1 Criteria

The concerns for adequately sampling mixed phases are more complex than those for homogeneous streams. Every component placed in the sampling train could prejudice the measurement system. Not only must the designer worry about the captured sample representing the process stream, but he or she must also be concerned with material-handling issues such as blockage, abrasion, erosion, and phase separation. The entire system must be monitored for correct operation, not only upon start-up, but also after the system has been placed in operation.

In general, there are many considerations to be made in the design of these systems, including: the mass flow rate of the material in the process line; the physical state (size and shape of particles, density, degree of wetting and phase ratios) of the materials; and the actual chemical composition of the sample. Other important factors to consider are whether an off-line method is to be used, what equipment is available to help move the sample, and whether the process is to be sampled continuously or at regular intervals.

The first decision to be made when sampling a heterogeneous stream is whether both phases need to be captured. Correct process operation may require the amount of an unreacted starting material which exists only in the fluid phase. In such an example, it is necessary only to extract the fluid – although both phases could be sampled if convenient. In cases where there is solubility of a reactant or product in two phases and the total needs to be known, both phases obviously need to be representatively captured.

5.2.2 Sample Stability

Another important consideration is whether the sample changes after it is removed from the process, and what can be done to prevent these changes. The sampling process itself could cause some speciation; if the probe design will not allow all species to enter the sample train with equal probability, segregation occurs. If the process stream has a significantly different flow rate than the sample train, solids may settle or emulsions may separate into different phases. As with samples from homogeneous streams, concern must also be given to the possibility of the sample reacting or decomposing once removed from the process stream.

5.3 Sampling Techniques

Sampling heterogeneous systems occurs either at a single point or across an entire section of process plumbing. Point sampling makes use of a single, well-defined sample point connected to the process stream. It is the preferred method for homogeneous systems that do not suffer from segregation effects. Although simple in design, this method often fails to yield reliable information about heterogeneous systems. Point sampling is prone to plugging, and relies on the heterogeneous system being very well mixed at its inlet. This technique is appropriate for fine dispersions of a denser material in a less dense medium.

Isokinetic sampling. If both phases are needed to yield the analysis appropriate for process control, it is important
that neither is excluded at the sample tap. For point sampling, it is important to have isokinetic sampling. In this methodology the velocity of the fluid flowing into the sampling inlet should be the same as the velocity in the process stream. In addition, the orifice into the sampling system should be aligned isoxially with the process stream flow, i.e. the process stream should flow directly into the sample tube. Discrimination occurs under nonisokinetic conditions because of the tendency of smaller particles to be pulled into the sampling orifice when its velocity is greater than the process flow rate, and the tendency of these same particles to move around the orifice when its velocity is slower than the process stream.

5.3.1 Cross-sectional Sampling

Cross-sectional sampling can be accomplished in one of three fashions: the entire contents of a cross-sectional volume could be moved from the process line to the sampling system; a slotted, sample-capturing device may be mounted across a section of the process plumbing; or multiple single-point devices can be installed to different depths within the process pipe. In the latter two cases, careful attention must be placed on the positioning of the probes in order to be certain that the sampling is not biased. In all cases, there is a better chance of capturing a representative sample if the tap occurs at a point where the process stream is well mixed.

5.4 Sampling Point Determination

Determination of the sampling point ideally relies more on production requirements for process feedback than it does on the analytical methodology. If the process property to be measured is available only within a small region of the process line or much of the process line has limited accessibility, the choice of sampling locations is limited. In addition, there are the more frequent requirements of lag time and required sample conditioning, which limit the choice of sampling location. Other points to consider are the ability to withdraw sample without interfering with the safe and effective operation of the process, as well as the installation of associated equipment needed to move the sample to an analyzer or sample vessel.

In order to sample a heterogeneous stream for laboratory or process analysis, one must have the ability to move the sample away from the process line to a vessel or analyzer and then move the stream to waste or back to the process. For less viscous samples, including many suspensions, emulsions, and slurries, the same flow considerations as for homogeneous fluid streams are made. For more viscous samples and streams with heavy solid loadings, care must be taken to include devices such as screw feeders to move a portion of the process stream into and through the sampling system.

Once a sample has been placed within the sample train, its representative nature must be maintained. Sample flow, temperature, and pressure may need to be controlled to achieve this goal. Additionally, equipment may need to be added to the sampling system to prevent blockage of lines. Finally, the entire sampling train needs to be compatible with the sample and the measurement objectives. Pumps, extruders, feeders, and other flow devices must be appropriate for the materials being monitored.

Maintaining these complex sampling systems requires a good deal of effort. Even in well-designed sampling schemes, systematic error or bias exists. Systematic measurement system bias is often largely due to the inability to capture a representative sample. Systems for heterogeneous processes, because of their complex nature, are more prone to these effects. Bias may occur because of design defects, temporary plant conditions, or aging of the sampling system itself. It is important to understand the bias of any system upon commissioning and to monitor changes in the bias over time. Because repeatability of the process analysis is very important for monitoring process changes, a slow change in the measurement system bias needs to be followed.

5.5 Sample Transfer

Transfer of heterogeneous samples can occur by many mechanisms. All of the devices used for homogeneous fluids, if appropriate, may be used, as well as devices specific for certain applications. Examples of other transfer devices are hoppers, conveyors, pneumatic devices, and metered feeders. Many problems are encountered in transferring heterogeneous materials, such as pluggage, abrasion, erosion, corrosion, and sample lag.

The flow characteristics of the sampled materials often dictate how the materials will be transferred to the sample vessel or analytical instrument. The densities of the components along with the velocity and viscosity of the fluid determine the likelihood of separation. Care must be taken to keep the velocity of the material in the sample transfer lines above rates where deposition or phase separation would occur. Insulation or heat tracing may also be required, depending upon the physical and chemical properties of the stream constituents.

The amount of sample to place in transfer lines depends on a number of factors. First, the amount of sample required to accurately represent the process stream must be considered. Next, one must ask whether the sampling process is continuous or interval sampling is used. In addition, one needs to consider the flow rates to the vessel or analyzer required to maintain the representative
nature of the sample. Finally, one needs to consider the pressure drop in the sampling lines and the flow and pipe dimensions required for a timely sample.

Successfully transferring and conditioning heterogeneous streams require more effort than performing the same functions for homogeneous streams. In general, line blockage is more likely to occur. Additionally, there are typically more components in a heterogeneous sampling system. The process streams also tend to be more demanding because of erosion and related processes.

5.6 Sample Conditioning

Sample conditioning requires that the sample be prepared for analysis or storage. The ultimate goal of the sampling system is to condition the sample without changing the important parameters of the sample. There are many modes by which a portion of the process stream may be changed once the sample has been withdrawn from the production pipe. Solids may be lost from flowing streams if the path is too tortuous. Liquid droplets may drop from a gas stream if the temperature drops or if the materials of construction are not appropriate. Line blockage may occur if the solubility of the material changes due to temperature or pressure effects. All these modes must be considered when determining the condition methodology.

5.6.1 Phase

When both liquid and gas are present in a process stream it is usually good practice to convert to a single phase. If possible, it is usually better to convert all species to the gas phase because of the ease with which the sample may be transferred and filtered. For many reasons, such as analytical methodology, liquid boiling point, decomposition, and reactivity, this is not always practical. Likewise, it is also not always easy to force gases back into solution because of pressure and safety concerns.

When other mixed phases occur simultaneously in a process stream, the primary goal is to be certain that the representativeness is not lost in the sample-conditioning process. If solids can be dissolved into liquids by raising the temperature (without losing description of the process), then an acceptable approach has been found. Such cases rarely, if ever, occur. More likely, effort should be placed toward ensuring that the sample stream remains well mixed and nonreactive.

A notable exception to this rule of thumb is when the analytical system requires dilution. Diluents may be added to the sample stream outside of the process pipe if there are no safety, control, or analytical concerns. Dilution is beneficial in many cases because either it may cause a single phase to result or it may allow for easier transport of the sample stream. Caution should be exercised, however, in the generation of large waste streams that cannot be recycled back to a process stream. Flow injection techniques have recently addressed a number of concerns regarding dilution or reaction of process streams prior to analysis.\(^{(55-57)}\)

5.6.2 Temperature and Pressure

As far as they affect the phase and therefore the representative nature of the extracted process sample, temperature and pressure are vital parts of sample conditioning. As with homogeneous systems, both stream properties often need to be controlled to be certain that samples can be withdrawn from and returned to the process. Control of these parameters also allows the analyzer to be presented with a recognizable sample, as well as keeping the sample train maintainable. In other cases, temperature extremes may be employed to quench reactions or to trap samples.\(^{(56,59)}\)

5.6.3 Filtering

Filtering heterogeneous streams while maintaining representativeness is a difficult task, especially in those systems containing solids. In some cases, one of the phases needs to be excluded for the analysis; in other cases, coarse filtering is preferred in order to digest one of the two phases. In still other cases, obvious portions of a sample stream, such as metal filings, rust, or zeolite drying column particles, are to be discriminated against. Where possible, one can aim to filter these materials from the bulk process stream components. In a select number of cases, filter elements may be used as sample-collection devices for subsequent analyses from heterogeneous streams.\(^{(56-62)}\)

6 SAMPLING SOLIDS

Solid process streams present many of the same sampling challenges as heterogeneous streams. Indeed, many solid process streams have a high degree of heterogeneity – solid particles are generally not of uniform size or composition. Because of these specific problems, sampling of solids needs to be considered as a separate topic. More detail for solid systems may be found in ASTM Standard E 877-93, which describes sampling of iron ores and related materials.\(^{(63)}\)

6.1 Design Considerations

6.1.1 Particle Size

In the production of solid materials, particles are distinguished by their size. The existing particle size
range in a process pipe determines the sampling system methodologies that could be employed successfully. It stands to reason that all minimal dimensions within the sampling train are dependent on the maximum particle size existing in the process stream. Also important are the particle shapes existing in the process line; it is generally easier to remove spherical particles from a flowing stream than elongated particles. Thus, the particle geometry as well as size will determine the orifice dimensions of the sampling port.

6.1.2 Mixed-phase Streams

When describing measurement systems for solid streams, often the details indicate that two phases are actually present. Fluidized beds usually contain solids and gases, whereas recrystallization vessels contain solids and liquids. In other cases, the solids may be wet from process liquids, or may otherwise contain entrapped fluids with the particle matrix. Additionally, solids are frequently suspended in liquid or gas streams to help move the particles down the process pipeline. In a great number of these cases one is interested in some characteristic of the solid, and the fluid phase is inconsequential. Typically, the sampling system designer must be aware of density differences and potential sources of density changes in order to build a reliable sampling system. Segregation frequently occurs in solid streams due to pathway differences arising from density and particle size variations.

6.1.3 Analyzer Requirements

Another key consideration in the design of these sampling systems is how the sample is analyzed. If the measurement is of particle size and distribution, great care must be taken to make certain that the analyzer receives a sample that is representative of the process. On the other hand, if the solid stream is to be pulverized, ground, dissolved, or digested, particle size integrity may not need to be maintained.

6.1.4 Erosion/Corrosion

The hardness of solid particles is also a point of concern. If the particles are relatively soft, poor uniformity of flow within and blockage of sampling lines might be a problem. With these types of materials it is very important to choose the motive components, such as pumps and conveyors, carefully. If the particles are relatively hard, erosion of sample transfer lines and associated components could become a serious problem. Once erosion does occur, corrosion usually becomes more likely because the active surface area exposed is likely to increase. Here, it is important to choose the materials of construction of the sampling train wisely.

6.2 Sampling Techniques

The sampling techniques used for heterogeneous systems are similar to those used for solid sampling. Either point sampling or cross-sectional sampling may be used in these systems, but one must understand the role that the transporting fluid, if any, plays in the conveyance process.

6.2.1 In-line

In-line analyses in solid process systems primarily focus on physical property measurements rather than on chemical composition. These systems also usually rely on a fluid phase for dispersion of the solid or as a part of the system. Examples of these analyses include turbidity and particle size measurements. Notable exceptions to this rule are some spectroscopic instruments such as diffuse-reflectance near-infrared spectroscopy, where the sample passes on a conveyor under a source and detector, or in microwave spectrometers, where the solid stream passes through a specially designed microwave chamber.

6.2.2 Extractive

Although some solids flow freely, extractive systems used to measure solids typically either have a motive force device, such as a screw feeder, or use a trap and purge method for moving the sample from the process stream to the sampling train. In addition to screw-based devices, gravity, suction, and sliding mechanisms are all used to partition a small fragment of the process stream contents into the sampling system. In other cases, a portion of the process stream is dropped or forced into a chamber, typically by an actuated sampler, and then transferred pneumatically to the sample collection vessel or process analyzer.

6.3 Sample Point Determination

Determination of the sampling point in these systems is similar to determining the sampling point in heterogeneous systems. The space, representation, and lag time concerns are the same for solids as for heterogeneous systems. The greater likelihood of solids segregating in the process line often makes the sampling process somewhat more difficult. Because the measurement system will never yield a better picture of the process than the sample that enters the sampling lines, the greatest concern in determining the sampling point is often how to represent adequately the bulk process in the capturing phase.
One must understand how the solids move within the process lines in order to choose an appropriate sampling point as well as appropriate techniques. If segregation does tend to occur in the process line, then it is typically beneficial to capture a cross-sectional sample of the horizontal pipe, or as an alternative to capture a sample on a vertical run of pipe as the sample falls through that section. A final alternative would be to use multipoint sampling across a range of the process pipe.

6.4 Sample Transfer

As with the transfer of heterogeneous materials, moving solids through sampling lines requires the use of appropriate devices for specific applications. When designing the sample transfer portion of the overall measurement system, one needs to be concerned with blockages, erosion, contamination between streams, and increased lag times, as well as safety.

6.4.1 Gravity

Because gravity is omnipresent in production processes, it is often used as an inexpensive motive force for transferring samples through sampling lines. A simple tee may be fitted into a horizontal process pipe. Within this fitting, a door leading to a chute could be connected that would allow samples to drop to a collection device or analyzer inlet. In a less ideal situation, a hopper could be inserted into this vertical line to help control feed rates through the sampling system. The problem with hoppers both within the process and in sampling lines is that there is a residence time range associated with these devices that causes not only greater overall lag times but also an increased time uncertainty related to process changes.

6.4.2 Devices

As mentioned previously, high-pressure inert gas may be used to move solids to an analyzer or sample-capturing device. These systems work well for fairly hard, small (<1 mm) particles, but may suffer from segregation and increased lag times due to dead spots and from increased erosion rates due to the increased kinetic energy of the particles. Conveyor belts, either alone or in conjunction with feeders, are also used to move solids along sampling trains. These other devices must be sized appropriately and designed with the analyzer conditioning requirements in mind.

6.5 Sample Conditioning

Preparing solid samples for analysis may require anything from trying to maintain particles as they existed in the process pipe to total dissolution in a strongly acidic solution. In some cases the solid materials are relatively inert to their surroundings, whereas in others the solids are reactive. Conditioning requirements may necessitate careful temperature or flow control. Temperature needs to be controlled in many cases if the sample is ground as part of the conditioning process, or if significant thermal changes cause changes in particle size or hardness.

6.5.1 Grinding

Many measurement systems require comminution, or size reduction. In processes where the measurement occurs after digestion of process particles, such as analyzing ore minerals by atomic emission in an inductively coupled plasma, comminution is desirable, if not necessary. Other analytical techniques might perform better if the solid particles are of a smaller, more uniform size distribution. Chopping, grinding, crushing, scraping, and cutting devices may all be used to reduce the size of process particles. Often, multiple devices are placed in a series configuration such that comminution takes place in controlled stages. The two major concerns of such devices are their ability to produce representative process samples and their need for maintenance.

6.5.2 Dissolution

Although much dissolution takes place in preparation for laboratory analyses, some systems make use of on-line dissolution. This is done for a variety of reasons: on-line analysis yields faster, more frequent results; the dissolution may be accomplished easily, with readily available solvents or reagents; and sample reactivity or safety concerns may lead to an on-line dissolution approach.

7 CALIBRATION AND VALIDATION OF SAMPLING SYSTEMS

As with any measurement plan, calibration and validation of sampling systems are vital to the value of the equipment. Calibration describes all the efforts made to determine the errors of the measurement system and the efforts placed into being certain that the instrument will yield a response proportional to the concentration of the species of interest. Validation is the quantitative performance of the measurement system and is typically accomplished by comparing the measurement system response to known or matched values.

The sampling train and sampling conditioning devices are part of the entire measurement system. As such, they must be considered when evaluating the analysis of a process sample. Because most analytical measurements are comparisons of responses to standards rather than
absolute indications, selection of calibration samples is of critical importance. These standards not only must reflect the variability of the process stream but also must represent the physical properties of the stream contents. This is an important point to note: different sampling systems and analyzers may respond differently to samples with the same constituent values but different physical characteristics. Typically, the best practice is to introduce calibration samples into the measurement system such that the sample undergoes the same conditioning as the portion of the process stream normally measured.

### 7.1 Frequency of Calibration

All sampling systems need to be calibrated before any process sample enters the architecture. This serves to reassure designers and users that the system will yield realistic results. Calibration prior to operation also allows various safety and other performance tests to be conducted before an actual sample is placed within the system. Once the error of the system is understood, one can make better judgements on the variability of the process as determined by the measurement system.

Recalibration, or at least verifying a calibration, should be performed periodically, with the periodicity determined by a number of factors. Systems prone to drifting or fouling should have calibration checks at least twice as frequently as these mishaps occur. If unusual results are produced by the measurement system, it is good practice to analyze a process sample by an independent analyzer; if disagreement exists, the process instrument system should have a calibration check. Some instrument manufacturers suggest calibration schedules as a part of preventative maintenance, whereas others have incorporated the means to manually or automatically send a calibration sample to the analyzer.

Instruments may be calibrated by the introduction of an external standard or may make use of internal standards added to a portion of the process stream within the sampling system. Although generally agreed to be a less satisfactory approach, the most common practice for recalibrating the measurement system is to draw a sample from the process stream, analyze the sample using a laboratory analyzer, and adjust the process instrumentation to match the laboratory measurement. When using this technique, one must understand the magnitude of the errors associated with both instrument systems in order to decide whether the results are significantly different. If any calibration verification shows the measurement system to be statistically the same, no adjustments should be made.

An important use of calibration is for validation. The instrument needs to be examined periodically in conjunction with the validation process. Once calibrated, the process analysis response can be tracked with control charts. This is truly the best method for determining drift in the measurement system. The calibration thus yields the starting point; once the starting point has been determined, the measurement system is judged on its bias and its repeatability.

An important practice in monitoring the performance of process analyzer systems, and hence sampling systems, is control charting. Control charting can be accomplished by measuring a standard sample periodically and plotting the results temporally. Figure 5 shows a series of control charts. Figure 5(a) shows a system exhibiting bias, where all (or the vast majority) of the responses obtained are greater than the control value. Figure 5(b) shows a system drifting over time. Although some drift may be acceptable, exceeding certain limits indicates the need for recalibration. Figure 5(c) shows a system with random error, or no net error. If the error values are of the same order as the precision of the instrument, this is a good indication that the system is performing well. If the errors in a control chart are more than three standard deviations of the noise, the system is said to be out of control, and some remedial action is required.

### 7.2 Long-term Performance

Tracking long-term performance of a measurement system requires documenting its calibration history. It
is often difficult to separate the performance of the sampling operation from that of the analyzer it supplies. When disparities exist between process and laboratory measurements, it is often the sampling system, not the analyzer, that has failed. Occasionally, the sampling system must be separated from the analytical instrument to determine the cause of failure. If the analyzer fails to provide an accurate measurement after being divorced from the sampling apparatus, the sampling system may still have failed in one of its missions, namely to provide the analyzer with a compatible sample. This must be determined and corrected, if necessary. If the analyzer yields adequate results after the sampling system is removed, the sampling system must be repaired or changed.

Determining the reliability of sampling systems requires a good deal of effort after the measurement system is initially started. The same is true whenever the sampling system has undergone changes. It is good practice to monitor continually the measurement system performance using control charts. This may be done using the control sample technique described earlier, or by comparing the process measurement against routine laboratory measurements by noting the differences between the two methods over time. Figure 6 shows a typical laboratory–process difference control chart where a drift is evident. As can be seen, the drift was eventually corrected through either recalibration or hardware maintenance. These types of control charts allow comparison over long periods of time and may indicate seasonal or process-related biases.

**8 MAINTENANCE**

Good long-term performance of sampling systems is a function of understanding the sample capture, transfer, and conditioning of the process stream as it travels through the train. Understanding these processes, their failure modes, and corrective actions is vital to the measurement system performance. A good measurement system will be operational for more than 99% of the time and be available to make process measurements well over 95% of the time. Reliable measurement systems will also have a relatively long mean time between failures.

**8.1 Design Criteria**

Sampling systems must be designed not only with the analyzer in mind but also with the end-user in mind. Components must be arranged so that the unit is maintainable by a skilled professional without the need for very specialized tools. Items commonly requiring attention, such as filters and valves, should be easily identifiable and accessible by maintenance personnel. The installation must meet all the necessary safety requirements of the production environment and be located in a convenient location. Recently, more attention has focused on the design of sampling systems for ease of maintenance by investigating component selection and modular construction.

Designers must specify the most appropriate components and materials before constructing the sampling system. Maintenance concerns are lessened if the designer conducts a thorough analysis of material compatibility issues between the process stream and the sampling system. In addition, common sense must be exercised when choosing the components. If a multifunctional device can replace multiple devices, it is generally good practice to incorporate the higher-functioning device. Examples are a flowmeter with a needle valve incorporated within the stem and a vaporizing regulator.

Ideally, alterations should not need to be performed after the sampling system is installed. Occasionally, changes will need to be made in order to accommodate changes in plant design or the addition of a sampling point, or for more reliable performance. All changes must be well documented, and the associated measurement system must be calibrated and validated as if the system were new.

Components of sampling systems should be as common and readily available as possible. The parts must be of robust construction, with the ability to withstand the rigors of the process stream and plant environment. In critical applications, there should be redundancy within the sampling system, or all the parts necessary to build a complete system should be on location.
8.2 Documenting Maintenance

Documenting the maintenance of the sampling system as well as the associated analyzer allows for faster determination of sources of error within the measurement system. Preventative, routine maintenance should be performed on a regular basis and documented. This allows for adjusting the frequency of maintenance to appropriate intervals.

9 SAFETY

9.1 First and Last Thought

The safe operation of any measurement system should always be the first and last thought of any sampling system designer. The sampling system must be designed appropriately for the process and environment it is to be installed in. Because its size relative to a process stream is small, sampling systems are more fragile. Safety devices incorporated within the process line, such as pressure-relief valves, must be included within the sampling system. Starting the sampling system should not cause hazardous conditions, nor should the shutdown cause any harmful events. If the potential for hazardous conditions cannot be avoided, every effort must be taken to minimize the risk for personnel. Release of chemicals should always be diverted away from locations where people may be found.

Only trained professionals must be allowed to work on sampling systems. These personnel must be well schooled in the safe operation of these systems. Tapping a process line while the process is operating through that line (hot tapping) should be a last-resort measure.

ACKNOWLEDGMENTS

The authors would like to acknowledge Eric Day for his help in preparing this article, especially the diagrams. We would also like to thank Sunita Saluja for her help in performing literature searches. Finally, we would like to thank AlliedSignal for its support of our efforts in process analytical chemistry.

LIST OF TERMS

At-line analysis Samples are withdrawn from the process stream and analyzed in close proximity to the sampling point.

Backflushing A multistream sampling technique where the selected process stream is used to flush out the non-selected sample lines.

Block and bleed A multistream sampling technique where the nonselected streams are blocked by an isolation valve and the tubing between this valve and the process analyzer is vented or returned to the process.

Bubble point The pressure at which volatile species in a process stream will form gas bubbles.

Bypassing A multistream sampling technique where the pressure differential between streams provides the isolation.

Cross-sectional sampling Extracting samples from varying positions in the process stream.

Cross-talk Contamination between process streams in a multistream sampling system because of poor isolation of the separate streams.

Dew point The temperature at which condensable gases in a process stream will form liquid droplets.

Double block and bleed Similar to the block and bleed design, but the incorporation of a second isolation valve provides for even greater isolation between the nonselected process streams and the process analyzer. The tubing between isolation valves and between the second isolation valve and the process analyzer is vented or returned to the process.

Fast-loop sampling A slip stream technique where a process pump is used to rapidly move the sample to a point near the process analyzer, and a fraction of this material is extracted for use in the analysis.

In-line analysis The analytical probe is placed directly in the process stream with no need for extractive sampling.

REFERENCES

Titration remains a method of choice for quantitation and assay because the techniques are simple and the repeatability and accuracy can be better than with other analytical methods. Titration has moved from the laboratory bench to the process in order to obtain more timely information for the control of the process. This has become possible with the development of sampling techniques for getting clean samples from a pipe or tank, sensors suitable for remote measurements, highly precise automated titrant delivery pumps, and microprocessor-based controllers adapting the time-honored methodologies of the bench chemist.

Topics discussed in this paper include theory, sampling techniques, titration control, detection and applications using pH, argentometric, redox, and photometric sensors.

1 INTRODUCTION

Many chemical plant operators desire on-line titrimetric analysis, because the analysis of samples directly in the process stream makes more timely data available for adjusting the process. A secondary consideration may be to improve overall efficiency, by automating manually supervised or manually performed analyses. In some cases a third consideration is that some samples deteriorate with time or exposure, and thus a shortened time to analysis improves the quality of the data. A fourth consideration could be to prevent contact between personnel and highly hazardous samples or reagents.

Titration is often the most accurate method of quantification. It may be the only practical method, or it may be the easiest method, or even the fastest of the available analytical methods.

Many analyses done titrimetrically in the laboratory can be done on line. Ideal conditions are homogeneous single-phase fluid samples at atmospheric pressure and room temperature, which are not excessively aggressive, and which react stoichiometrically with a titrant. Particles in the stream, high temperatures and pressures, and aggressive or corrosive characteristics of the sample complicate the sample pretreatment. Solid samples are not good candidates for process titration. The difficulty is with the repeatable measurement of a quantity of sample, because solid samples can normally not be measured by volume and must be weighed on a balance. Assays of solid samples are better done individually in the laboratory with manual or with automated titration techniques. Many attempts have been made to automate the weighing process using robotic systems, but these are so maintenance intensive and complex as to limit them to supervised laboratory environments.

2 THEORY

Titration is a batch process. The basic principle of titrimetric analysis is that the portion of interest of the
sample will react quantitatively with a titrant of known concentration. The course of the titration is tracked with a sensor that detects the equivalence point, at which sample is fully reacted. There must be a mechanism for measuring the amount of sample and delivering it to the titration vessel. There must also be a means of measuring the amount of titrant added. When the analysis is finished, the vessel is flushed to prepare for the next measurement cycle. The calculation assumes that the equivalent amount of sample is equal to the equivalent amount of titrant (Equations 1 and 2):

\[ N_S \times V_S = N_T \times V_T \]  

or

\[ \text{milliequivalents of sample} = N_T \times V_T \]  

where \( N \) is the normality or equivalents per liter, and \( V \) is the volume in milliliters. A typical expression of concentration may then be written (Equation 3) as

\[ \text{content(\%)} = \frac{N_T \times V_T \times M}{10 \times Z \times (V_S \text{ or } W_S)} \]  

where \( M \) is the molecular weight and \( Z \) is the valency change, \( V_S \) represents the sample volume in milliliters (in which case one calculates percent by volume), and \( W_S \) represents the weight in grams (in which case weight percent is calculated). Introducing the sample density \( \delta \) in grams per cubic centimeter, one can calculate weight percent using a volumetric sample (Equation 4):

\[ \text{content(\%)} = \frac{N_T \times V_T \times M}{10 \times Z \times V_S \times \delta} \]

3 INSTRUMENTATION

3.1 Overview

The titration system must perform the processes of sample treatment, sample measurement, addition of solvents and reagents, the titration consisting of two interacting processes, sensor measurement and titrant addition, and cleanout. A control computer or built-in microprocessor controls these processes and provides an interface to the operator and to the process computer (Figure 1).

3.2 Sample Pretreatment

Precise analytical titration requires known amounts of homogeneous sample. In the real world of pipes and flowing streams, samples often require some pretreatment to obtain a measurable homogeneous sample. This may include filtration, separation, pressure reduction, degassing, and temperature adjustment. A flowing stream may have solid particles that can destroy valve surfaces, it could have dissolved salts that will precipitate out as the temperature drops, it may be under pressure and when that pressure is released degassing could occur, and it may have a hydrocarbon phase and an aqueous phase – these may need to be separated and analysis done on one or the other.

Extracting a representative sample from a process stream for subsequent analysis involves some compromises. It is rare that a sample is sufficiently pristine that it can be fed directly to the inlet of the desired instrumentation. On-line titration is no different in this regard. To derive meaningful information about the process the sample must often be purified without corrupting the analyte, or by changing it in such fashion that the degree of difference from ‘true process conditions’ is known.

3.3 Sample Handling

3.3.1 Extraction

The first step in the chain of operations to obtaining meaningful on-line measurements is determining how to gain access to the process stream. It is desirable to design a sample-handling system that uses the minimum number of additional devices. There are many options.

Process Pump Probably the most desirable option is to tap across an existing process pump. This approach takes advantage of the fact that the capital expenditure (and maintenance responsibility) for the pump have been catered for. In such an arrangement, a sample port is added to exit piping, routed to the desired analyzer location, and back to an inlet port on the upstream side of the pump (Figure 2). Samples obtained in this manner are well mixed by virtue of their passage through the
pump. The main disadvantage of this approach is that large process changes are recirculated through the fast loop and can lead to an increased analysis lag time. If such lag times are a problem, the recycled sample must be reintroduced into the process downstream of the take-off point at a low-pressure point in the process.

Process Pressure If no convenient pump is available, but the process is under sufficient pressure, it may be possible to introduce an in-line connection at a high-pressure point. The existing process pressure provides the drive energy to force the process sample to the desired analyzer location, and back to a lower-pressure process point. It is tempting to make use of existing process connection points (blind flanges) to provide the connection points. However, extreme care must be taken in such cases to avoid various types of sampling problems. Blind side-arms on piping runs typically are mounted at right angles to existing piping. If the piping run to which connection is desired runs horizontally, such right-angle mounting may place the side-arm on top of the pipe, on the side of the pipe, or on the bottom of the pipe (Figure 3).

Any or all of these may present potential sampling problems. If connection is to the top of the pipe, gas bubbles will be preferentially routed into the sample line. If connection is to the bottom of the pipe, suspended solids will be routed preferentially into the sample line. The preferred connection is to a side-arm mounted on the side of the pipe. Even then, there is the probability that the volume of the side-arm will introduce significant time lags, as it represents a large, stagnant volume of process fluid that must be diluted out by the sample flow. With the addition of a properly designed stinger, any of the aforementioned side-arm piping orientations becomes a viable sample point (Figure 4). Note the shape of the end of the stinger, and its orientation with respect to process flow. This arrangement allows some extra discrimination against bubbles and/or particles flowing down the pipe. The stingers illustrated are all for the take-off point of the sample flow – the return point is not shown, being located further down the process or at some other low-pressure point.

Dedicated Pump The use of a dedicated pump to provide flow through the fast loop to the analyzer is usually not a popular option. It represents both an additional capital cost, and additional maintenance costs. Also, when such a pump fails, its replacement will always be a low-priority item compared to other maintenance emergencies, with increased analyzer downtime and decreased analyzer reliability as a result. However, a dedicated pump does provide several advantages in that it can be much smaller and less expensive, and does not require multiple taps into the process for extraction and return points (Figure 5).

The arrangement shown in Figure 5 shows the use of a flat plate style cross-washed inertial filter. Systems of this sort are usually plumbed up with piping (and dedicated pump) sufficiently large to allow the largest solids in the process to completely traverse the fast loop piping. This usually requires that the fast loop be three quarters to one inch (16 to 25 mm) pipe. With the addition of some automated valving and a different stinger style, this arrangement becomes a fairly sophisticated means of sample prescreening for larger particles – thereby allowing the use of a smaller cross-washed filter and
3.3.2 Transport

Extraction of the sample from the process pipe is only the first step in the chain of events that must occur before quantitative information can be derived from the on-line titrimetric analysis. Once withdrawn from the process, the sample must be transported to the physical location of the instrument. Whether this transport is done with a process pump, process pressure, or dedicated analyzer pump, several factors must be observed.

**Sample Integrity** It is critical that the samples do not change significantly, or that any change is not detrimental to the quality of the analytical results or to the reliability of the instrument. In the sample transport step, the most likely parameter to change drastically is temperature. Many processes operate at elevated temperatures, and the extraction and transport processes can result in fairly drastic drops in temperature. As many process streams of interest in on-line titration may be fairly concentrated solutions, such temperature drops can result in solid material precipitating out of solution, with catastrophic effect on the sample system. Temperature drops can also result in shifts in chemical equilibrium, which can lead to a measurement result that differs from the true concentration of the target species in the process. Sometimes the reverse situation occurs—a grab sample is taken from the process and analyzed, yielding a substantially different result from the on-line instrument. In many cases, the error arises from a chemical change that has occurred in the grab sample. Finally, depending on the climatic conditions, cooling in transfer lines may be sufficient to allow sample freezing to occur. Depending on the specific process and situation, it may be necessary to insulate or provide heat to the transfer lines.

**Time Lag** The introduction of fast-loop piping (and other sample processing devices) introduces various time lags in the analytical results. An exhaustive treatment of the possible sources of lag time is beyond the scope of this article, but such time lags must be a consideration when designing and using the sample handling system. The closer the analyzer to the sampling point, the shorter the sample travel and the smaller the time lag, the better.

3.3.3 Physical Conditioning

Successful transport of the sample from the process is only the second step in the chain of events that must occur before quantitative information can be derived from the on-line titrimetric instrument. For most samples, further conditioning is required.

**Filtration** The presence of suspended solids is possible in any process system. Even high-purity water systems may have particulate matter resulting from piping or pump wear, so the addition of a filtration step ranges...
from being highly desirable to absolutely essential. If the sample stream contains very low levels of particulate matter, it is possible to use in-line cartridge filters and simply change the filter element based on a time interval or by measuring pressure drop across the filter. However, if the levels of suspended particulate are higher, then cartridge-type filters will clog up too quickly, resulting in unacceptable maintenance requirements. The criteria for effective filtration must include not only how effective the particular filter is for removing particles above a certain size, but how long the time interval is between any sort of maintenance (changeout or backwash). The most useful type of filter is a cross-washed inertial filter (Figures 5 and 6), as these provide greatest reliability and minimize maintenance.

Gas Removal Many sample streams either contain bubbles, or contain dissolved species that form gas bubbles on removal from the process (usually due to the drop in pressure from process pressure towards ambient pressure. If the initial quantity of sample to be analyzed is determined volumetrically (as for instance by using a sample-loop injection valve), the presence of bubbles can contribute to significant analytical errors. There are two approaches to removing bubbles – bubble separation based on gravity and/or wettability, and membrane extraction. Gravity-based methods can handle very high quantities of formed gas bubbles, but are relatively ineffective at removing dissolved gases. The inverse is true for membrane extraction methods. Probably the best approach is to combine the two methods in series, with a gravity-separation device to remove the vast majority of formed bubbles, followed by a membrane device to remove any remaining dissolved gas. These two approaches are less suitable for cases where foam is present. Foams can sometimes be broken by forcing the foam and liquid through a porous element, and doing a gravity separation downstream of the unit.

Dissolution The sample stream may contain solid material whose presence contributes to the measured variable (an example is an alkaline stream containing sodium bicarbonate, where the desired titration measurement is total alkalinity). Sampling these types of streams is particularly difficult. What is usually done is to use some sort of valve to isolate a relatively large volume of the sample containing both liquid and solids for transport to the titration vessel. A standpipe sampler is shown in Figure 7.

In operation, the sample flows from the process into the inner cylinder of the device, filling it and overflowing to the drain. At some desired time interval, the three-way valve is actuated, blocking flow in from the process, and dropping an isolated aliquot of sample into the titration vessel.
sample loop or with a motor-driven piston burette. Using a piston burette has the drawback that, as it has some dead volume, numerous complete strokes are required to completely purge the syringe. The piston burette is subject to fouling and the sample must be free of particulates and precipitable components. It has the advantages that the sample is measured quite precisely and that the volume of sample taken can be varied to accommodate various sample strengths. A valve-operated pipette is used for fixed-volume samples of moderate to large volume (5–50 mL). It is similar in operation to the Standpipe Sampler (see Figure 7). A two-position six-port injection valve can be used to set up a sample loop with the volume dependent on the length and internal diameter of the tube used to make the loop (Figure 9). In the first position, flow comes from the process through the loop and back to the process. To deliver the volume of the loop, the valve is moved to the second position and water or solvent pumped through to flush the contents into the titration vessel. Very small volumes can be sampled accurately with this method, typically from 0.1 mL up to 5 mL.

### 3.4 Titrant Delivery

Two types of pumps are commonly used in titrators. The glass-barrelled burette with a Teflon® piston can deliver very precise volumes at a controlled speed. The precision of delivery is typically better than 0.05% relative standard deviation (RSD) on a full burette volume. A valve is required to direct the flow from the reservoir and to the delivery tip. The other type of pump has a ceramic sleeve with a rotating piston. The piston has a cut-away face that exposes, alternately as it travels in or out, the outlet port and inlet port. The precision achieved by this pump is not as good as with the glass-barrelled syringe-type pump, but it will purge thoroughly with less volume, has fewer moving parts and can be run with one motor. The glass-barrelled syringe-type of pump requires two motors, one to drive the piston with a precision spiral-cut gear, and the other to turn the valve.

The ultimate in precision is only achieved when there is a controlled release at the dispensing tip. An open tube type of tip, even of a very small diameter, will allow exchange of titrant with the solvent of the titration vessel. Various methods have been used to control this exchange (Figure 10). The tip path can be run in a convoluted fashion, reversing direction of a small-diameter tube; alternatively, an insert can be put in the tip with a flapper type of valve. Another approach is to have a straight Teflon® tube with a razor-cut longitudinal slit which is normally closed but opens under the pressure of the pumped titrant. Another way is to squeeze shut the heated end of a Teflon® tube so that the tube closes but does not seal. The two flaps appear a bit like the bill of a duck, and open under pressure.

### 3.5 Titrination Control

The earliest automatic titrators simply delivered titrant until a preset potential measured on an electrode was reached. The volume was read and the result calculated. Somewhat later, volume delivery was coordinated with a chart recorder and the electrode reading drawn on a moving chart. The chart was evaluated for an inflection point on the curve. In state-of-the-art titration systems, computers control the titrant delivery and evaluate the data. A set point evaluation takes the volume at a particular pH or potential read by a sensor, either an electrode or a photometric detector. Typically there is some control, to deliver rapidly when far from the set point and to slow down as it is approached. This can be achieved by adding consistently small increments of titrant and allowing longer time between increments as the set point is approached. Another way is to vary the size of increments in a dynamic fashion, based on the slope of the curve. When the slope is flat, the increments are large, and when the slope increases, the increments decrease in volume. In this fashion, titrant is delivered rapidly when far from the region of interest and slowly near the

Titration of HCl with NaOH

Figure 11 Titration with inflection point marked.

equivalence point. The end-point evaluation is based on being able to consistently have a set point or to find an inflection at or near the equivalence point, that point where the titrant and the analyte are in equal valence proportions. The timing of the titrant delivery may be strictly on a time basis, proportionally to approaching a set point, or based on the stability of the measured signal (equilibrium control). The more sophisticated titrators allow a combination of these timing schemes, such as the signal attaining a set equilibrium within a time window. The next increment is delivered either when the electrode signal is stable or at the end of the time window.

Inflections may be evaluated in several ways. The most common evaluation for potentiometrically measured titrations and many photometric titrations is to the center of an inflection. That is the point where the curvature changes direction (Figure 11). In some photometric titrations, the point where either the color begins to change or ceases to change is the desired point. The evaluation is for the intersection of two lines, the steepest part of the curve and the straight line where there is no color change before or after the color change, respectively. This type of evaluation can also be applied in conductivity titrations, when the rate of conductivity changes relative to titrant delivery changes because an absorbing element in the sample is saturated. For certain types of turbidimetrically detected surfactant titrations, surfactant activity can be detected by the maximum or minimum of turbidity generated by an immiscible two-phase mixture.

3.6 Titration Curve Shapes

The shape of the titration curve affects how well the inflection point can be anticipated. Well-behaved acid–base titrations have a predictable curve and the equivalence point can be estimated from a few points at the beginning of the titration. The titration can be conducted rapidly at first, then slowed proportionately as the inflection point approaches. If time is of no consequence, one can titrate a reaction with slow kinetics over a long period of time. However, in industrial analysis, time is often of the essence, and a rapid titration is pressed with some sacrifice of accuracy. In many oxidation–reduction titrations indicated with a platinum combination electrode, only a small shift in the electrode potential heralds the coming inflection point, which usually has a large jump in potential. The titration thus must be done with smaller increments than might be used on a comparable acid–base titration. This is often even more pronounced with dye indicators (Figure 12). Indicators that develop an absorbance might at first be diluted with the addition of titrant, thus increasing the transmittance. Then as color begins to change, the transmittance decreases abruptly, thus producing a titration curve with practically no possibility of anticipating the end-point. Therefore, the titration must be done with small increments in order to get an accurate result.

3.7 Sensors

Sensors can be potentiometric electrodes, conductivity detectors, polarizing electrodes, or photodetectors. The most commonly used potentiometric electrode is the glass electrode pair for detection of hydrogen ion activity, or pH. Electrodes are always in pairs; there must be a reference electrode and a sensing electrode. Today combination electrodes are made which have the reference electrode built into the same measuring rod that holds the glass sensor, but there are still two electrode half cells. The hydrogen electrode is defined to have a potential of zero, against which all other electrodes are referenced. However, it is not easy to use and is usually only used for certain types of research.
3.7.1 Reference Electrodes

The reference electrodes in common use are the silver–silver chloride half cell, the calomel half cell, and the Orion Ross™ reference electrode (Orion Research, Beverly, MA, USA). The calomel mercury cells are not much used because of the hazards associated with mercury. Most reference half cells are based on the reversible silver–silver chloride reaction on a silver wire suspended in an electrolyte solution. A low-flow ceramic frit or ground glass junction allows electrical charge transport via ionic travel between the electrolyte solution inside and the measured solution outside of the electrode. A clear flow path is essential as a clogged flow cuts the flow of ions and thus, charge, affecting the measured signal. Various modifications of the standard ceramic frit plug can improve the flow. These include an annular fritted ring, both fixed or movable ground glass joints, and a spring-tensioned movable glass joint. The standard electrolyte is potassium chloride saturated with silver chloride for the silver–silver chloride reference electrode, and potassium chloride for the Orion Ross™ reference electrode or calomel half-cell. If other electrolytes are required for compatibility with some part of the measured solution, a double-junction reference may be used where the upper chamber has the silver chloride-coated silver reference wire and potassium chloride saturated with silver chloride. A ceramic frit junction connects to the lower chamber, which may be filled with an appropriate electrolyte such as potassium chloride, lithium chloride in alcohol, potassium nitrate, or potassium perchloride.

The most common causes of reference electrode failure are clogging of the flow path by a solid-forming reactant such as silver ion precipitating with chloride, by clogging with oils or polymers, and by contamination with ammonia which dissolves the silver chloride on the silver wire. A silver–silver chloride reference electrode filled with a potassium chloride solution must have the electrolyte saturated with silver chloride; otherwise, the potassium chloride solution will dissolve the silver chloride. This electrolyte must be avoided for the Orion Ross™ reference electrode or the calomel reference electrode as the silver will poison these reference electrodes.

3.7.2 Glass Electrodes

Glass electrodes (pH electrodes) are sensitive to the presence of hydronium ions. The pH-sensitive glass is composed of silicon oxide doped with various alkaline earth metals. The addition of lithium or lanthanum to the silicon improves the selectivity and response to the hydrogen ion. When this glass is placed in aqueous media, the surface swells to form a hydrated layer. Proton transfer occurs at the phase boundary between the glass and the hydrated layer. A potential develops which is proportional to the hydrogen ion activity in the sample. Because this potential is a very weak signal, the measurement amplifier must have a very high input impedance so that it will draw very little current, so as not to corrupt the signal.

Care must be taken to ensure proper hydration of the glass. Protein, oil or polymers, which may coat the glass, must be removed, either mechanically by wiping or through the use of chemical solvents. If the electrode is used in media that dry the hydrated layer, such as the petroleum acid number solvent, which is composed of 49.5% toluene, 49.5% isopropyl alcohol, and 1% water, the hydration must be restored by soaking the electrode in water for 3–5 min between samples. Proper maintenance of the pH sensor will ensure accuracy and promote longevity of the electrode.

3.7.3 Temperature Correction

For accurate pH measurements when the sample temperature is different from the calibration temperature of the electrode, a Nernst correction must be applied to correct for the temperature dependency of the slope of the electrode. However, most acid–base titrations are indicated by the detection of an inflection point or by a set potential titration at a steep part of the titration response, and thus an exact pH is not necessary for an accurate titration. More important for an assay could be the temperature-related expansion or contraction of the titrant relative to its standardization temperature. This is approximately 0.1% at 25°C for a 5°C deviation from the standardization temperature with an aqueous titrant, and about four times that for an organic solvent-based titrant.

3.7.4 Redox Sensors

A platinum or gold electrode will detect the oxidation potential of ions in a solution. The potential swings are typically quite large, and the small deflection of the titration curve before the inflection is less pronounced and the jump, when it comes, more sudden than with aqueous pH titrations. Usually somewhat smaller titration increments and a more sensitive anticipation detection system must be used if a variable-increment titration is performed. The reference electrode most commonly used is silver–silver chloride. Iodometric or bromometric titrations may also be detected with a polarized conductance detector consisting of two platinum electrode elements and either a constant current (voltametric) or constant voltage (amperometric) current source. The conductance measured is dependent on the presence of both iodine and iodide, or bromine and
standard addition method works by adding aliquots of known measurement of ionic activity, for a Gran’s plot–standard addition method.

3.7.5 Argentometric Sensors

Titrations using silver nitrate to quantitate halides such as chloride, bromide, or iodide, reactive sulfur compounds such as hydrogen sulfide or mercaptans, or cyanide, can utilize a metallic silver electrode. In the case of halides, the electrode follows the silver ion concentration, which is necessarily low when halides are present as they combine to form an insoluble precipitate, and high when the halides have all been combined with silver and a slight excess of silver added. The reference typically used is a silver–silver chloride half cell filled with 10% potassium nitrate solution. For sulfur compounds, the electrode must be sensitized to sulfide by depositing a layer of silver sulfide. The potential follows the reactive sulfur concentration, which drops as silver ion is added. The same reference may be used as for the halide titrations, but the reference electrode may be subject to clogging by silver mercaptide, silver sulfide, or oils. For petroleum crude oils and for distillate fuels, a glass half cell may be used as the reference. For clean petroleum distillates, a sulfide-specific electrode may be used, which is based on a crystalline matrix containing silver sulfide. Cyanide titrations follow the same pattern as the halide titrations, except that the tightly bound silver cyanide complex is soluble and no precipitate is formed.

3.7.6 Specific Ion Electrodes

Electrodes have been developed with sensitivity to various species. In general, if an electrode will give a rapid and stable response, it can be used for titration. Some commercially available electrodes are shown in Table 1.

Specific ion electrodes may be used for direct measurement of ionic activity, for a Gran’s plot–standard addition method or for conventional titration. The standard addition method works by adding aliquots of known concentration of the ion in question and observing the potential change measured on the electrode. The original concentration can be calculated from the potential change relative to the amount of added ion.

3.7.7 Photodetectors

Photodetectors have several advantages over potentiometric electrodes, including faster response, better long-term reliability, and usability in low-polarity non-aqueous solvents. However, a stable indicating dye must be available which will indicate the reaction under investigation. The sample must be optically clear and free of suspended solids, it must not generate gases or precipitates, and it must not leave deposits on the detector windows.

Three types of photodetectors are available for titrimetric analyses. All use optical fibers to carry a light source to the detection point, where there is a light path through the solution. The light path can be direct or reflected from a mirror, with a return optical fiber light path to the detector. In one system a wide-spectrum incandescent light is reduced to a relatively narrow band with an interference filter in order to focus on one particular absorption window. In another system the light source is a light emitting diode (LED) which emits light within approximately a 15 nm band. The beam is chopped by switching the LED on and off, and the measured signal is compared to the background light. Another design uses two LED sources at different wavelengths in order to null out differences in optical density of the sample solution as the titration proceeds. In some cases, a dual-wavelength detector can be set with one wavelength where the indicator will decrease absorption, and the other wavelength set where the indicator will increase absorption, and thus improve the detected signal.

Optical detectors can be used to follow a titration and for color development analysis, such as the analysis for phosphate using barbituric acid. The photometric titration curve is typically different from potentiometric titrations in its curvature and also in that, in many cases, it is the point where the color begins or ceases changing, rather than the inflection point, which is sought.

3.8 Cleanout

At the conclusion of a titration, the vessel must be drained and rinsed prior to the next sample coming in. This is typically achieved by either a dedicated drain port at the bottom of the titration vessel (see Figure 9) or a small tube which goes to the bottom of the titration vessel through which the sample is aspirated. Water or solvent can be piped from a pressurized reservoir, and the flow controlled by a solenoid-operated valve, or it can be propelled by a pump.
3.9 Communication

The results are typically computed in the titrator. Depending on the set-up, they may be transmitted to a printer or to a process control computer via a serial output, such as current loop or RS232 or RS488, via a local area network, or via an analog output such as 4–20 mA. The systems may be under control of the process computer, with a start titration signal sent by a digital signal line or by serial port, or the titrator may run autonomously on its own timing.

3.10 Waste Generation

When hazardous solvents or samples are involved in the analysis, it becomes advantageous to design the system to run smaller samples in order to minimize the waste generated.

3.11 Maintenance

If a titrator in a process situation is essential for the operation of the process, there should be trained maintenance personnel with parts readily available. The electrode fluid level and titrant and reagent levels should be checked on a regular basis, possibly daily or every 3 or 5 days.

3.12 Isolation and Explosion Proofing

In locations with flammable fumes or products it may be desirable to eliminate spark sources. A titrator should meet all local requirements for isolation and explosion proofing. For example, instead of using electrically driven pumps and valves, one might use pneumatically driven pumps and valves. The electronics, including the burette motors, may be enclosed and purged with an inert gas.

3.13 Commercially Available Titrators

At the time of this writing (1999) there are several manufacturers of on-line process titration instruments. A partial listing of these is in the acknowledgement section of this article.

4 CHEMISTRY

4.1 Reaction Kinetics of Titrant–Analyte Reaction

Several factors are important to getting a good analytical titration. The electrode must deliver a signal dependent upon the concentration of either the analyte or the titrant. This signal must be rapid relative to the speed of the overall titration, and it must accurately depict the progress of the titration. The speed of the reaction is important, as well as that the reaction must go well to completion. A fast reaction such as the reaction of acidic protons with alkaline hydroxyl ions in aqueous solution or the reaction of chloride with silver(I) ion can be followed readily. A reaction of hydroxyl ion with saponifiable epoxide groups will not run quickly to completion, so the usual procedure is to add a known excess of the reactant, then allow the reaction some time, perhaps under an elevated temperature, and then, when the reaction is complete, the excess hydroxyl ion is titrated with an acid. A similar situation may occur when attempting to titrate sterically hindered amines with perchloric acid. The reaction is too slow to be easily titrated within a reasonable time, so an excess of perchloric acid is added, followed by a reaction time and back-titration of the excess perchloric acid with sodium acetate.

4.2 Solvent

The kinetics of the electrode response and the stability of that response are strongly influenced by the polarity of the solvent in which the titration is carried out. A polar solvent such as water ionizes the reference electrolyte and allows rapid ionic travel, and thus, efficient charge travel between the measuring electrode and the reference electrode. A nonpolar solvent such as hexane will not permit enough ionic movement to carry an electrode signal. Alcohols provide usable polarity. Acetic acid is used as a solvent for the nonaqueous titration of bases using perchloric acid. The acetic acid forms the acetate with many bases, and in a sample containing mixed bases most will titrate under a single inflection point. The perchloric acid can titrate weak bases that are difficult to measure by other methods. The preferred reference electrode fill solution is potassium perchlorate in acetic acid, although lithium chloride in ethanol works quite well. Pyridine may be used as a nonaqueous solvent for titrating acids using tetraethyl ammonium hydroxide. With a mixture of carboxylic acids with different acid dissociation constants, one inflection is usually obtained.

The polarity of the solvent affects how well the inflection points of mixtures of analytes can be separated. When the polarity is high, as with water, acetic acid, or pyridine, the inflection points of mixtures tend to form either one single inflection or a poorly separated series of weak inflections due to dissociation in the solvent. If the titration can be carried out in a solvent with lower polarity, the sample is less dissociated and the various constituents will form better-defined inflection points. Thus, a titration of citric acid in water shows only one inflection point, but in n-propanol three inflection points are detectable. Sulfuric acid in water shows one inflection point, but in a mixture of toluene and isopropyl alcohol, the inflections due to the two different protons are clearly
separated. The drawback in this last titration is that the speed of charge travel is restricted in the low-polarity solvent and one must titrate very slowly in order to allow the electrode sufficient time to equilibrate.

4.3 Sensor Kinetics

The speed of the sensor response can influence the titration. The titration speed must be such that the sensor gives an accurate portrayal of analyte status. A slow-responding electrode, such as an ammonia electrode which measures pH changes brought about by gaseous ammonia permeating a Teflon® membrane, requires a commensurately slow titration. A fast-responding electrode, such as the silver electrode in a silver nitrate-halide determination, makes possible a rapid titration. If the electrode response is slow and the titration is done too quickly, the end-point or inflection point will be overshot, thus yielding a high result. In nonaqueous acid-base titrations a glass bulb electrode will usually respond slower than in an aqueous environment. The ionic charge travels slower in a less-polar medium. Likewise, measuring an absolute pH in low-ionic-strength water such as rainwater requires more time for stabilization than when working with high-ionic-strength seawater or mineral acids or bases. Indicator dyes in photometric titrations are usually selected to have a fast reaction, and the speed of response becomes dependent on the efficiency of the stirring.

4.4 Indicators

Indicators in some way point to the equivalence point. Visual indicators are dyes, for instance litmus or phenolphthalein, which change their color absorption at various levels of the target species, such as hydrogen ion concentration. Permanganate, by virtue of its deep purple color, can be self-indicating. A visual observation of an iodine titration end-point can be sharpened by the addition of starch, which forms a blue-black complex with iodine. Mercuric EDTA (ethylenediaminetetraacetic acid disodium salt) [139-33-3] can be used to indicate a calcium or hardness titration using a mercury-sensitive electrode.

4.5 Materials Compatibility

When planning to measure samples on line by means of titration, it is essential to consider the compatibility of the sample with the wetted materials of the titrator and sample handling system. Teflon® valves are used where possible, and stainless steel is avoided when analyzing strong mineral acids. Glass electrodes and components must be avoided when analyzing acidic fluoride. Nonaqueous solvents can swell or alter polymeric components. Glass is dissolved, albeit slowly, by strong aqueous bases.

4.6 Environmental Impact

Safe and environmentally compatible disposal of waste is an important concern with any chemical operation. Titration of cleanwater samples with sulfuric acid for carbonates generates a small quantity of nontoxic salts. This can safely be disposed of in a public sewer. However, if the sample contains heavy metals, or if the titrant contains silver or mercury, it may be poisonous to biological water treatment systems and must be treated as a hazardous waste. Titrations in nonaqueous solvents generate waste which may vaporize and be a hazard to personnel on-site if not disposed of safely. If the titration can be done effectively on a smaller scale, less hazardous waste is generated per sample with correspondingly reduced disposal costs. This approach is not effective for nonhomogeneous samples, where a large sample size is necessary to obtain a representative sample. Small sample size must also be weighed against the need for precision, where the repeatability of measuring an aliquot is better with larger sample sizes.

Consideration must be made for any vapors which may issue forth from the solvent, sample, or titrant. Vapors may be flammable, explosive, or poisonous. The hazard involved should be assessed and provision made for dissipation or entrapment of the vapors. Chemical absorbing filter systems work well and the filters are readily disposed of.

5 APPLICATIONS

5.1 Aqueous Acid–Base Titrations

In water, electrode-induced titrations are predictable. There is usually enough ionic activity to transmit ionic charge in the solution and the glass sensing electrode will rapidly and repeatably indicate the hydrogen ion level (pH). A base such as sodium hydroxide may be titrated with an acid such as sulfuric acid with repeatability better than 0.05% RSD (Figure 13). The exception to this is with low-ionic-strength samples such as rainwater, which must be titrated slower and possibly with a Gran’s calculation. Industrial samples typically have adequate ionic strength for titrimetric analysis. If they do not, a small amount of potassium chloride may be added to increase the ionic strength.

The titrants typically are stable for long periods, but periodic standardization is good practice for best accuracy. Bases may be standardized with potassium acid phthalate (KHP). Acids are typically standardized with tri(hydroxymethyl)aminomethane (THAM). Alkaline titrants should be protected from atmospheric carbon dioxide by blanketing under nitrogen, storing in a sealed, collapsible bag-type vessel, or by filtering with
Figure 13 Titration of sodium hydroxide with sulfuric acid.

an alkaline filter made of ascarite or moisture protected sodium hydroxide pellets. In practice there is not much difference between using sulfuric or hydrochloric acids. Hydrochloric acid will evaporate, sulfuric acid will not. It is possible to standardize the titrant of an on-line titrator by making provision for volumetric introduction of a known standard, or one can take a grab sample and compare the lab analysis using standardized titrants with the on-line analysis. Table 2 shows some examples of aqueous acid–base titrations.

5.2 Nonaqueous Acid–Base Titrations

There are a great variety of nonaqueous acid–base titrations, many of which are not suitable at all for process titration. The reasons usually relate to the electrodes not being stable. A glass pH electrode must have the outer surface hydrated in order to be stable and have an optimum response. Good candidates for process titration are easy titrations, such as acidity in alcohols, or acid or alkaline strength of samples which can be readily mixed with low-molecular-weight alcohols such as methanol, ethanol, or propanol. Analysis of amines in ethanol typically works quite well. Unlike aqueous solutions, titrations to a set pH do not work well in nonaqueous media. The absolute potentials are not stable. However, the titration curve usually has a repeatable shape. Therefore, the end-point of the titration can repeatedly be found by seeking the inflection point. If needed, the electrode can be hydrated with a water cycle between samples. Petroleum titrations, such as acid numbers, base numbers, and neutralization numbers, can normally only be done in the laboratory because the electrodes require frequent attention. The same case exists with the analysis of sulfides and mercaptans in petroleum samples by titration with silver nitrate. The electrodes are too finicky for process analysis.

Bases are typically standardized with KHP and acids with THAM. The exception is that perchloric acid in glacial acetic acid is typically standardized with KHP because it is acidic enough to titrate the phthalate as a base. Nonaqueous titrations are always evaluated to an inflection because absolute potentials are not as stable as in aqueous solutions. Table 3 shows some examples of nonaqueous acid–base titrations.

5.3 Redox Titrations

Oxidation–reduction (redox) reactions can be used for a wide range of sample analyses. The sensing system used

is usually a platinum combination electrode. Analyses can be direct, such as the case of analyzing hydrogen peroxide with potassium permanganate (Figure 14), or indirect, such as the reaction of chlorine with iodide, which forms iodine and is subsequently titrated with potassium thiosulfate. Typically the solution is made strongly acidic. Table 4 shows some examples of redox titrations.

#### 5.4 Argentometry

The most common argentometric titration is the analysis of chloride. Chloride content is often correlated to salt content in chemicals, food, or waters. The argentometric titration employs a silver combination electrode that measures the level of silver ion added as silver nitrate in a neutral to acidic solution. Although there is free ionic chloride present, it combines with the silver ion forming silver chloride, which precipitates, thus taking the silver out of solution. As the chloride ion concentration diminishes, the silver ion level begins to rise. This behavior can be expressed as the solubility product, $K_{sp}$, Equations (5) and (6):

$$ \text{Ag}^+ + \text{Cl}^- \rightarrow \text{AgCl} \quad (5) $$

$$ K_{sp} = \frac{[\text{AgCl}]}{[\text{Ag}^+][\text{Cl}^-]} \quad (6) $$

When the chloride is all combined with the silver, the silver ion concentration rises and the silver electrode measures a steep rise, which forms an inflection point (Figure 15). The amount of silver added thus corresponds to the amount of chloride added. This analysis is not specific to chloride, as bromide, iodide, and cyanide will also react with silver. In a mixture of iodide, bromide, and chloride the titration curve will have three inflection points, in that order. However, each inflection point does not necessarily reflect a stoichiometric reaction of silver with only one halide species. Chloride will also react in the region associated with bromide, making this an inexact analysis. The pH of the solution is important – it must be neutral to acidic; the analysis will not work under alkaline conditions. Usually an acid such as sulfuric, nitric, or acetic is added to bring the pH to the range 6–2. If the acid is too strong, it dissolves the silver in the indicating electrode. This dissolved silver will react with halides, thus lowering the apparent halide content. Cleaning the precipitated silver chloride may be a problem as it clings to electrodes and stirrers unless a small amount of nonionic surfactant such as Triton X-100 is added to break up the precipitate. Table 5 shows some examples of argentometric titrations.

#### 5.5 Complexometric Titrations

Complexometric titrations using EDTA may be used for a variety of divalent cations, such as zinc, copper, cadmium, nickel, and iron, but the most common analysis is the colorimetric determination of hardness. Hardness is determined in water treatment plants. The sample is buffered to pH 10 and Eriochrome Black T indicator added. The EDTA chelates the calcium and magnesium in the sample. At the end-point, the EDTA concentration rises and causes the indicator to change from blue to purple. A colorimetric detector senses the color change. Magnesium can be masked by adjusting the pH to 12 with sodium hydroxide, and then titrating only the calcium. Other divalent cations may

Process analyzers based on selective ultraviolet (UV) and/or visible (VIS) absorption provide highly reliable on-line composition monitoring and closed-loop control throughout the process industries. Design criteria for ultraviolet/visible (UV/VIS) analyzers are different to those for laboratory instruments since the process instrument must meet the area electrical classification and often withstand harsh plant environments such as vibration, wide temperature swings, corrosive atmospheres and “dirty” samples.

The designs of various types of UV/VIS process analyzers are reviewed, and applications of these analyzers in major process industries are described.

1 INTRODUCTION

On-line composition analyses based on selective UV and/or VIS absorption have been used for process monitoring and control throughout the process industries for over 60 years.

New and improved UV and VIS light sources, detectors, interference filters and optical materials continue to be developed, expanding the potential for UV/VIS analyzer applications. Process analyzers using a linear photodiode-array detector (LPDAD) and holographic gratings have been developed to provide multicomponent and selective analyses not previously feasible.1

2 BRIEF HISTORY

During the past half century of design evolution, photometric analyzers based on UV/VIS absorption have found increasingly wide applicability throughout the process industries. UV/VIS analyzers were among the first plant stream analyzers used for direct monitoring of process stream composition and for closed-loop control.

Before 1930, Kurt Müller, in Germany, developed one of the first UV analyzers to monitor elemental mercury in air, using the mercury 253.7-nm atomic resonance line as the measuring wavelength.2 In effect, it was an atomic absorption measurement. In 1939, Woodson et al. of General Electric (GE) also described a sensitive mercury analyzer using a GE G4T4 low-pressure discharge lamp as the source for the 253.7-nm line.3

Until the late 1950s, most UV analyzers were developed within petroleum and chemical companies for proprietary use, and a few were designed at university research facilities. Many of these early instruments either used the 253.7-nm mercury resonance line from a germicidal lamp as the measuring wavelength or adapted the Beckman DU laboratory spectrophotometer.

Some of the early UV/VIS analyzers performed adequately, were well applied and filled needs resulting in substantial savings. However, others were poorly designed for continuous plant service and were often misapplied. As a result of some of the early failures, it took almost a generation for some process companies to accept UV/VIS analyzers (and plant stream analyzers in general). The split-beam photometric analyzer was developed by DuPont in the mid-1950s initially to meet the need for accurate monitoring and control of chlorine gas concentration in the “chloride” process for producing titanium dioxide.4 In 1962, about 200 of these instruments were applied within the DuPont Company when the commercial version was introduced as the first product of the newly formed Instrument Products Division. Other UV/VIS photometric analyzers, particularly the Analytic Systems (now Teledyne) photometric analyzer and the Halikainen UV analyzer, were commercially available and used by several companies at that time. However, the introduction of the split-beam analyzer, with its large application base within the DuPont Company, greatly expanded the use of photometric analyzers throughout the process industries.
3 PROCESS VERSUS LABORATORY INSTRUMENTS

In contrast to a laboratory UV/VIS spectrophotometer, the process analyzer is designed to be used in a plant environment for the continuous or semicontinuous analysis usually for a specific component critical for process or environmental control. Whereas most laboratory UV analyses are on liquid phase samples, the bulk of process UV analyses are in the vapor phase. The measuring wavelengths used in process UV analyzers are most often provided by isolating an emission line from a metallic discharge lamp. Since the emission line is at a fixed wavelength and extremely narrow, the analyzer output can be highly linear with concentration based on Beer’s law even if the measuring wavelength is away from an absorption peak. If the UV/VIS analyzer is used in an automatic control loop, high reproducibility with a minimum of dead zone may be essential, and the instrument usually must respond rapidly to changes in concentration. Hence, delays through long sampling lines must be avoided.

The problems associated with continuous sampling in a plant environment are usually formidable, and design criteria for process stream analyzers go well beyond those for the laboratory. Criteria used in designing UV/VIS process stream analyzers, developed from plant experience, have been described previously and include rugged construction, serviceability, the accuracy, stability and reproducibility required for the application, linear and rapid response, and simplified sampling requirements.

Most process UV/VIS analyzers have separate light source, sample, and photometer housings. The three housings of the analyzer are easily separated, and the analyzer is readily adapted for monitoring process gas and liquid streams in pipeline cells installed directly in the process line. This modular construction permits the use of special cells such as those used with high- or low-temperature gas and liquid samples.

In recent years, the elements used in UV analyzers have been greatly improved. Advances in thin-film technology have resulted in more stable interference filters with higher resistance to temperature and improved transmittance with narrower band-passes. “Quieter” discharge lamps with longer lives are now available, and silicon photodiodes have been improved for use in the UV region with high signal-to-noise ratios and temperature resistance equivalent to that of vacuum phototubes. Highly pure quartz with high transmittance throughout the UV/VIS region is now available for windows, lenses and fiber optics, and other optical glasses are being developed.

4 TYPES OF PROCESS ULTRAVIOLET/VISIBLE ANALYZERS

Several types of process analyzers based on UV/VIS absorption are commercially available. These instruments range from very simple to highly sophisticated designs. The types of analyzers described in this section are not the only commercial UV/VIS absorption analyzers, but are the most prevalent units used in industrial applications. Process UV/VIS analyzers may be divided into two basic types: (1) filter photometric analyzers and (2) spectrophotometers. Included in the filter photometer category are single beam, split-beam and “filter wheel” analyzers. Scanning spectrophotometers (with fiber optics) and process diode-array analyzers are the significant types of spectrophotometers used in process applications. Process UV analyzers based on étalon technology were introduced; however, since none are now commercially available, they will not be discussed.

4.1 Filter Photometric Analyzers

Filter photometric analyzers are the most common kind of process UV/VIS analyzers, and the simplest is the single-beam type; a functional diagram is shown in Figure 1. The output of this type of instrument will be affected by fluctuations and drift of the light source, dirt or bubbles in the sample cell, and any drift in the detector or detector circuit. As a result, single-beam instruments must operate on relatively low sensitivity (high absorbance) levels to provide reasonably stable analyses. Stabilized light sources and improved detector circuits, in recent years, have improved stability to some extent, and these simplified units are being used in applications such as the detector for semicontinuous colorimetric analyses where frequent automatic ‘zero’ adjustment is provided.

![Figure 1 Functional diagram of single-beam analyzer.](image-url)
A functional diagram of a typical split-beam analyzer is shown in Figure 2. This type of design is based on simultaneous differential absorption measurements at two wavelengths and has several distinct advantages, including compensation for dirt and bubbles in the sample cell. Radiation from the source, generally a metallic discharge lamp, is partially absorbed on passing through the sample. The radiation leaving the sample is divided into two beams by a semitransparent mirror. Each beam passes through an optical filter to a photodiode. The filter removes radiation at all wavelengths except the one to be measured. Radiation at the analytical wavelength is absorbed strongly by the measured component. Radiation at the reference wavelength is absorbed weakly or not at all by the measured component. Each photodiode develops a current directly proportional to the intensity of radiation striking the photodiode. Each photodiode current is converted into a DC voltage proportional to the negative logarithm of the photodiode current, providing signals linear with concentration based on Beer’s law. The output voltages are fed to a microprocessor which provides digital and analog outputs calibrated in concentration units.

Figure 3 is a functional diagram of a filter-wheel chopper photometric analyzer. The filter wheel contains two or more interference filters (at different selected wavelengths) continuously rotated by the chopper motor sequentially into the optical path. The source light is collimated by a series of lenses and directed through the filters and the sample cell. A detector lens focuses the transmitted light on to the detector. The detector provides electrical signals proportional to the intensities at each wavelength. As in the split-beam analyzer, two wavelengths are used for a single concentration measurement; however, if more filters at selected wavelengths are used, multiple concentrations may be measured. The analyzer microprocessor is programmed to compensate for overlapping absorbances.

Using the new improved UV elements, several manufacturers of infrared (IR) filter photometric analyzers have been able to convert the basic optical bench of the IR analyzer for use in the UV/VIS region. The functional diagram in Figure 3 is typical of ABB Process Analytics, Ametek–Western Research and Anarad analyzers and several others.

The Ametek–Western Research analyzer uses up to three separate hollow-cathode sources with a system of
mirrors to provide several discharge lines from these lamps as measuring wavelengths. Figure 4 is a functional diagram of the Ametek–Western Research Series 900 analyzer.

4.2 Process Ultraviolet/Visible Spectrophotometers

It was realized early in the development of photometric analyzers that a laboratory scanning spectrophotometer could not be installed in a process plant environment with any acceptable degree of reliability. The optical bench of a spectrophotometer with an LPDAD is much less complex than that of a scanning spectrophotometer, where an optical element must be moved to provide spectrum intensities to a detector.

Process scanning UV/VIS spectrophotometers have optical benches functionally the same as those used in the laboratory but use fiber optics to transmit radiation through the sample cell from the monochromator to the photomultiplier detector. In general, the monochromator and the detector are installed in a clean, electrically classified “general-purpose” area with the sample cell in the plant area. Practically all of the uses for the process UV/VIS scanning spectrophotometers are for applications in the VIS and the near-UV region since the quartz in the fiber optics may have limited transmittance and can be “solarized” with time in the far-UV region. A computer, usually with chemometric software, is used with the spectrophotometer to provide the required output signals.

Process photodiode-array analyzers have been developed and applied for process control and emission monitoring. The optical assembly of the LPDAD spectrophotometer used in a process analyzer has no moving parts (except for a shutter in one design), and its detector assembly is compact and particularly rugged with superior signal-to-noise ratio performance and overall quality.

The process diode-array spectrophotometer shown in Figure 5 uses a deuterium lamp source, operating...
at a reduced current and emitting a broad spectrum of radiation (light) from the vacuum-UV to the very near-IR region. The light is collimated and directed through the sample cell to the detector assembly where the light is focused on to a slit, striking a holographic grating which disperses the light on to the LPDAD. The grating is precisely positioned with respect to the diode array such that each diode sees light a fixed number (or fraction) of nanometers apart. High-resolution versions extending from 190 nm are used for source monitoring.

5 APPLICATIONS OF PROCESS ULTRAVIOLET/VISIBLE ANALYZERS

Thousands of process UV/VIS analyzers are being used throughout the process industries for environmental and process control. In some applications where the UV analyzer is used in a feedback control loop, the process may be inoperable without the analyzer.

Process UV/VIS analyzers are used extensively for monitoring of source emissions, particularly for sulfur dioxide (SO$_2$) and nitrogen oxides (NO$_x$) concentrations. Other pollutants monitored by UV/VIS analyzers include ammonia, elemental mercury, aromatic compounds and elemental halogens.

In petroleum refining and in gas production, process UV/VIS analyzers are used extensively for control of the Claus sulfur recovery process. Rapidly responding analyzer systems monitoring both the SO$_2$ and the hydrogen sulfide (H$_2$S) concentrations in the tail gas provide an output for feedback control of the air to the Claus furnace to maintain the optimum 2 : 1 ratio of [H$_2$S] to [SO$_2$]. Process UV analyzers are also used to monitor the H$_2$S concentrations in the Claus plant feed and in the “lean” amine in the sulfur removal process.

The transmitted color grade is a primary quality measurement in petroleum refining, and process photometric analyzers are used extensively to monitor color grades from the very dark tars (Tag–Robinson color scale) through the refined oils (ASTM D-1500 color scale) to the hydrocarbons (Saybolt color scale). Process UV/VIS analyzers are used in a large variety of applications in the petrochemical and chemical industries. For example, elemental halogens, particularly chlorine, with ranges of 0–50 ppm to 100% are monitored in gaseous and liquid phases. Chlorine has a broad absorption over a wavelength span covered by few other materials. Materials of construction in contact with a halogen sample must often be carefully selected. Teflon®, Hastelloy C-176, nickel, etc. have been used in these applications. Synthetic sapphire windows are used where fluorine or hydrogen fluoride are present.

Precise control of many chlorination processes, such as in dichloroethane production, in phosgene manufacture, and in the titanium dioxide chloride process, have been made possible through the accurate measurement and control of chloride concentration.

In general, oxidizing agents have strong absorption bands. Materials such as sodium hypochlorite (NaOCl), chlorine dioxide (ClO$_2$), hydrogen peroxide (H$_2$O$_2$), ozone (O$_3$), and potassium permanganate (KMnO$_4$) are examples of oxidizing materials whose concentrations are monitored with process UV/VIS analyzers. “Bleaching” steps can often be controlled by the monitoring of the oxidizing agent concentration.

Concentrations of aromatics in aliphatic hydrocarbons are monitored in very low concentrations, and unit processes for removal of the aromatics are often controlled with this sensitive measurement. In the manufacture of polycarbonates, bisphenol-A [2,2-bis(4-hydroxyphenol)-propane] is continuously monitored.

Liquid color grading scales other than those used in petroleum refining include APHA (American Public Health Association), Rosin, Hazen and ICUMSA (International Commission for Uniform Methods of Sugar Analysis). Process photometric analyzers have been calibrated for each of these (and other) color scales and are successfully and accurately monitoring the color of a variety of liquid products on the specified color scale.

Several of the streams are monitored at very high temperatures (>200°C) and pressures (>150 bar).

Salts of transition metals such as iron, nickel, manganese, vanadium, and copper are usually strong absorbers and are monitored for process control.
In several chemical processes, sulfur-containing compounds such as SO\textsubscript{2}, H\textsubscript{2}S, carbonyl sulfide (COS) and carbon disulfide (CS\textsubscript{2}) are monitored and controlled for safety and process efficiency. In pharmaceutical processing, antibiotics generally have strong UV absorption and are being monitored with process UV analyzers. When the valuable product is collected after separation in a large process liquid chromatographic column, a process UV analyzer may be used to provide the concentration information required to determine when to start and stop the collection of the product.

The largest application of photometric analyzers in the production of wood pulp for paper is the monitoring and control of ClO\textsubscript{2} in bleaching operations. ClO\textsubscript{2} is highly corrosive, and the only satisfactory materials of construction in contact with the sample have been titanium, fluorocarbon resins and ceramics (quartz and glass). Vapor-phase ClO\textsubscript{2} in percentage concentrations is highly explosive and should not be heated. It is also readily photochemically decomposed when exposed to wavelengths below 420 nm, and it is advisable to install a titanium flame arrester between the analyzer system and the process.

UV photometric analyzers are used to monitor lignin concentration in brown stock and for control of pulp digesters.

6 CALIBRATION AND SAFETY ISSUES

In practically all gas-phase applications of UV photometric analyzers, Beer’s law is precisely followed up to 1.5 absorbance (and often higher) if the measuring wavelength is a narrow line from a metallic discharge lamp. Hence an accurate initial analyzer calibration may be provided with only one or two prepared concentrations of the gas to be analyzed. It should be noted, however, that the calibration gas should be at the same regulated temperature and pressure as the sample will be in the field. Without absolute pressure control, the accuracy of a gas analysis may be limited to ±2% (because of barometric pressure changes). With a dual-wavelength, single-component analysis, an optical glass with a differential absorbance equal to that of an upscale concentration of the measured component may be inserted into light path (with “zero” gas in the sample cell) to give a quick but accurate check of the analyzer span.

For multicomponent analyses with overlapping absorptions, initial calibration can be highly time-consuming since an extensive calibration set of concentrations of the components must be fed to the analyzer to establish the correlation analysis software and to confirm the validity of the software package.

Often, process streams with UV/VIS-absorbing compounds are toxic and/or explosive, and special safety precautions must be taken when calibrating or working on the analyzers. It should also be noted that UV sources, such as a low-pressure mercury discharge lamp, may produce low levels of VIS light but intense UV radiation highly dangerous to human eyes. Safety glasses will block the most dangerous low-wavelength UV light and should always be worn when working with UV analyzers. However, even with safety glasses on, one should avoid exposure to the source radiation, which can also be damaging to the skin.

The pulp and paper industry is a major player in the economies of many developed countries. As illustrated in Figure 1(a) and (b), the developed world accounts for more than 60% of the world output in pulp, paper and paperboard capacity. In one particular case, namely Canada, the industry contributes over 15% to the trade balance (see Figure 2). In order to ensure continual survival of the industry, it is necessary to continually improve and/or optimize the utilization of raw materials, the pulping processes, the papermaking process, the product quality properties and the protection of the environment. Analytical chemistry has an important role to play in the improvement and/or optimization of these parameters. This article summarizes how and where analytical chemistry is used, or can be used, to achieve the desired goals. Applications of analytical chemistry in the pulp and industry are reviewed in detail in the rest of the articles in this section on pulp and paper.

1  WOOD CHEMISTRY

Wood is the main raw material for the manufacture of pulp and paper. Its components can be divided into two groups, viz. macromolecular and low molecular weight substances. Macromolecular substances are the major constituents and they include cellulose, hemicelluloses and lignin. Cellulose (1) determines the character of wood fibers and enables them to be used for papermaking. It is a polysaccharide of glucose units with the formula \((\text{C}_6\text{H}_{10}\text{O}_5)_n\), where \(n\) is the number of repeating sugar units or the degree of polymerization. Hemicelluloses are polysaccharides of five different sugars from hexoses (glucose, mannose, galactose) and pentoses (xylose and arabinose). The hemicelluloses are susceptible to more degradation and dissolution than cellulose during chemical pulping. Lignin is an amorphous, highly polymerized substance that cements fibers together. It is a very complex polymer consisting primarily of \(p\)-hydroxyphenyl, guaiacyl and syringyl groups that are linked together in a three-dimensional structure and whose concentrations differ in softwoods and in hardwoods. A simplified structure of a partial softwood lignin molecule is shown here (2).

The low molecular weight components are minor constituents that include pectins, extractives and inorganic matter. Although minor, these materials nonetheless do have major impacts on the pulp and papermaking processes. For example, lipophilic extractives (fatty acids, resin acids, glycerides, sterols, waxes, etc.) account for about 2–5% of the weight of wood but cause or contribute to process upsets (pitch deposition problems) that cost the North American industry upwards of $200 000 000 annually.

Analytical chemistry plays a major role in understanding the chemistry of the wood. For example, one of the major chemical differences between softwoods and hardwoods is the presence of resin acids (diterpene acids) in softwoods and not in hardwoods. In general lipophilic extractives are comprised of fatty acids, resin acids, glycerides, sterols, waxes, etc.) account for about 2–5% of the weight of wood but cause or contribute to process upsets (pitch deposition problems) that cost the North American industry upwards of $200 000 000 annually.

Analytical chemistry plays a major role in understanding the chemistry of the wood. For example, one of the major chemical differences between softwoods and hardwoods is the presence of resin acids (diterpene acids) in softwoods and not in hardwoods. In general lipophilic extractives are comprised of fatty acids, resin acids (softwoods only), fatty acid ester glycerides, waxes, sterols, steryl esters and alcohols, as shown in the example structures (3–9). Analysis of the extractives has shown that they are important in facilitating or hindering the pulping and papermaking process. For example, the resin acids in softwoods are easily saponifiable during chemical pulping and consequently are easily removed from fibers by washing with water. This is one of the reasons why softwoods are the main source of fibers for chemical pulping. hardwoods lack resin acids and, consequently, are difficult to process by chemical pulping. Normally pulping of hardwoods is done after storage of the wood for some time. The storage results in a decrease in the amount of wood resin in the wood. In addition, the chemical pulping of hardwoods is facilitated by addition of the wood resin (tall oil) collected from mills that pulp softwoods.\(^1\) Here analytical chemistry plays a role by monitoring the chemistry of the wood resin with storage time. For example,
compounds that cause the most pitch deposition problems are reduced by storing the wood prior to pulping.

In addition, analyses of wood and bark show that bark contains 5–6 times more wood resin than the wood itself. This is one of the reasons why good bark removal is a prerequisite in pulp and paper manufacture. Wood resin is known to contribute to the toxicity of mill effluents. Hence mills are required to monitor for their presence in effluents to ensure that their effluent treatment systems remove them adequately. In analyzing wood extractives, the main analytical tools are gas chromatographic techniques (see Pyrolysis in the Pulp and Paper Industry).

Microscopic techniques are used to characterize the morphology of wood fibers. Thus, softwoods can be differentiated from hardwoods by the size and dimensions of the vessel elements. Fibers from softwood are longer than fibers from hardwoods, and this is why they are the main wood species for making printing, writing and packaging papers. Wet chemical methods are used to study the nature of wood, for example, to differentiate sapwood from heartwood by staining techniques.
The chemistry of cellulose and hemicelluloses in wood and pulps has been studied by wet chemical methods and instrumental methods such as spectroscopy and chromatography. In mechanical pulp furnishes, the pulping processes release substances from the wood that are cationic and subsequently compete with papermaking additives that such retention aids. Controlling or minimizing the cationic demand is an important concern in papermaking. Studies by Finnish scientists have shown that pectin polysaccharides such as glucomannans are major contributors to the cationic demand in mechanical pulp furnishes. Analysis by gel permeation
chromatography revealed that these pectic substances have an average degree of polymerization of 130. Their identification led to the development of a pectinase enzyme aimed at destroying the compounds in pulps.

2 WOOD PULPING

Wood is debarked and then cut into wood chips before pulping. The main pulping processes use mechanical and chemical processes to yield mechanical and chemical pulps.

2.1 Mechanical Pulps

Mechanical pulps are produced by mechanical grinding action on wood chips or wood, in the presence of water, to produce pulp. The pulp yields are very high (>95%) because very little wood components are lost in the aqueous matrix. Mechanical pulps are used to produce lower grade products such as newsprint, catalogs, paperbacks, wrapping papers and paperboards. These products do not require paper with high-strength physical properties. Mechanical pulps contain lignin and this material causes the paper to yellow in the presence of light (see Mechanical Pulps, Ultraviolet/Visible Spectroscopy of Chromophores in). Controlling the yellowing process can significantly increase the value of mechanical pulps and this is where analytical chemistry comes into the picture. The complex structure of lignin has challenged researchers to develop suitable methods to characterize the material. Methods that have been used encompass classical and spectroscopic analytical techniques. For example, chemical degradation of lignin with alkaline nitrobenzene yields large amounts of aromatic aldehydes, namely p-hydroxybenzene, vanillin and syringaldehyde. This degradation method is extensively used to classify lignins from different wood species according to the amounts of the aldehydes generated. Spectroscopic methods that have been used to study the structure of lignin include ultraviolet (UV), infrared (IR) and nuclear magnetic resonance (NMR) techniques. UV spectroscopy has been used to monitor UV-absorbing functional groups (e.g. aromatics), IR for estimating the ratio of guaiacyl to syringyl units in lignin and NMR for the quantitative determination of functional groups such as aliphatic hydroxyl, phenolic hydroxyl and benzyl alcohol groups. The lignin has to be extracted from wood or pulps before analysis and several procedures have been developed. One typical extraction scheme for obtaining lignin from pulp is shown in Figure 3.

2.2 Chemical Pulps

Chemical pulps are made by cooking wood chips in chemicals such as caustic soda with sodium sulfide. The caustic soda dissolves most of the lignin from the wood matrix; consequently, the pulp yield from such a chemical pulping process is about 50%. In addition, some cellulose and hemicellulose compounds are dissolved during the cooking process and this is an undesirable occurrence because it results in pulps with lower than optimum papermaking properties. To optimize the cooking process, analytical chemistry is used to measure and evaluate parameters such as alkalinity, total titratable alkali and permanganate number (extent of lignin removal). The integrity of the pulps is determined by measuring their cellulose and hemicellulose contents. Cellulose is measured by chemical degradation methods or by gel permeation chromatography. Hemicelluloses can be measured by their depolymerization (enzymatic or otherwise) followed by analysis of the depolymerized monosaccharides by high-performance liquid chromatography (HPLC), anion-exchange chromatography or gas chromatography (GC). In recent years capillary ion electrophoresis has been increasingly used to analyze for carbohydrates in pulp and paper matrices (see Carbohydrates from Chemical Pulps: Characterization by Capillary Zone Electrophoresis).

After cooking, the cooking chemicals are removed and the pulp is washed free of the chemicals with water. This washing is an important step that is carefully monitored by measuring the concentrations of the cooking chemicals in the wash water. The cooking chemicals are sent to the recovery furnace where they are regenerated for reuse in the pulping process.

2.3 Recycled Pulps

Recycled or recovered paper is now a major source of fibers in papermaking. The recovered paper is reslushed and the printed ink removed, typically by a flotation process. A major problem with recycled paper is the presence of nonfiber components such as plastics, glues,
adhesives and pressure-sensitive labels. These materials tend to be tacky and stick to process equipment and the paper products, causing tears and holes in the products. Consequently, mill productivity is lowered by these contaminants because the papermaking process is shut down to remove and clean the contaminants from mill equipment. Analysis of these contaminants has shown that they include a diverse list of compounds (see Pyrolysis in the Pulp and Paper Industry). To minimize their impact on the pulp and papermaking process, it is important to ascertain their concentrations in the incoming furnish and their removal efficiencies in mill process cleaning unit operations.

Methods that have been used to analyze the contaminants in recycled fibers include Fourier transform infrared (FTIR) spectroscopy, solvent extraction, gel permeation chromatography, NMR, GC, pyrolysis/gas chromatography (Py/GC) and pyrolysis/gas chromatography/mass spectrometry (Py/GC/MS).

3 BLEACHING

Chemical pulps require bleaching to remove residual lignin that was not removed in the cooking process. The bleaching process results in a white pulp that is suitable for printing and writing papers such as copier grades, legal and government documents and high-quality books. The bleaching can be done with elemental chlorine-free reagents such as hydrogen peroxide, oxygen and ozone. In earlier years, chlorine was the main bleaching chemical until, with the help of analytical chemistry, it was ascertained that the chlorination led to the formation of chlorinated dioxins and furans that were detected in pulp and paper products and in mill effluents. Switching to a nonelemental chlorine bleaching process eliminated the presence of chlorinated compounds in pulp and paper matrices.

Since mechanical pulps are used in the production of lower grades of products, there is no need to remove the lignin present in the pulps. In any case, attempting to remove them by bleaching would be a very expensive process. Instead of bleaching, some grades may be brightened by partial removal of lignin, addition of tinting dyes and addition of fluorescent agents that will make the paper products appear brighter. Such brightened pulps are used mainly in making paper for printing books.

4 PAPERMAKING

After pulping and bleaching or brightening, the fibers are now ready for conversion into paper. To achieve this, a number of additives are added before, during and after the papermaking process. A partial listing of additives and their purpose is shown in Table 1.

To ensure efficient and optimal addition of additives, it is important to monitor for their concentrations in the paper or water matrix. In some cases, the additives Table 1 Partial listing of additives that are used in pulp and papermaking processes

</table>
may be deactivated before reaction with the paper. For example, alkyl ketene dimer sizing agent can hydrolyze to yield products that are very tacky and can cause process upsets by causing the paper to tear. The dissolved and colloidal substances in process waters are negatively charged. Consequently, they compete with fibers for cationic additives (e.g. retention aids) added in the papermaking process. Knowing the types and concentrations of these negatively charged compounds would be of help in optimizing the addition of additives. These negatively charged compounds have preoccupied papermaking chemists for a long time and recently analytical schemes have been devised to characterize them in process waters. For example, one method entails centrifugation of a pulp suspension to remove fibers, collection of the supernatant, liquid–liquid extraction with a nonpolar solvent, derivatization of the extracted compounds and analysis of the derivatized extracts by GC techniques.\(^{[7]}\)

Another way to determine the effectiveness of additives is to install deposition plates in the process stream and then wait for deposits to accumulate on the plates. The plates can be periodically monitored visually for cleanliness, giving the operators an idea of what is happening in the process. The analytical chemist will remove the deposits to conduct chemical analyses that will determine the chemistry of the material that will have accumulated on the plates.

### 5 QUALITY CONTROL

A persistent problem in pulp and papermaking is the presence of dirt spots in the products. Pulp and paper products that are contaminated with the dirt spots have to be culled or sold at below premium prices. A wide variety of compounds can lead to the formation of these unwanted contaminants; they include pieces of bark, fly ash, lipophilic extractives, metal soaps, defoamer components, sizing agents and fillers. A good chemical analysis of these contaminants include: spot tests (e.g. fizz test with acid to show the presence of calcium carbonate); ash content to determine if the contaminants are organic or inorganic; FTIR spectroscopy to determine the major functional groups present; solvent extraction schemes to separate components such as defoamer oils, wood resin, metal soaps, hydrolyzed size; and chromatographic techniques to understand the chemistry of the separated components. If the contaminants are present in large quantities, then a variety of analytical methods can be used to obtain information about their composition. In some instances, the contaminants may occur as dirt spots that are visible to the naked eye but too small for adequate analysis by techniques that require solvent extraction. In such instances, microanalytical techniques are used. For example, an FTIR instrument with a microscope attachment can be used to analyze very small samples of dirt spots or paper with very little sample preparation required (see **Fourier Transform Infrared Spectroscopy in the Pulp and Paper Industry**). Another technique that is useful for such small quantities is Py/GC where the samples are pyrolyzed to yield pyrolysis products that are subsequently analyzed by GC techniques (see **Pyrolysis in the Pulp and Paper Industry**). For semiquantitative determination of inorganic matter, microscopic techniques, specifically energy-dispersive spectroscopy, can be used.

Microscopy is a powerful complementary technique in the analysis of pulp and paper samples, as illustrated in the following example. Our laboratory was asked to ascertain the cause of poor print quality of a newsprint sheet made by one mill. Printing a solid black image on the sheet resulted in tiny white spots, all over the image, that measured about 2 mm across. Obviously the mill customer was not happy about this and sent back the shipment of paper. A visual examination of the sheet showed that there were what appeared to be fiber bundles in the nonprinted areas of the sheet. Examination of a nonprinted sheet also showed the presence of the fiber bundles. The fiber bundles were collected from the sheet using tweezers with the aid of a magnifying glass. Several of the spots were analyzed by FTIR spectroscopy and their spectra were compared with each other and with the spectrum of the good part of the sheet. The data showed that all the spectra were identical and indicated the presence of cellulosic matter. The spots were then analyzed by Py/GC/MS and, again, their pyrograms were identical with that of the good part of the sheet, showing that there was no difference in their chemical makeup. Finally, analysis of the fiber bundles by scanning electron microscopy (SEM) showed that the bundles were actually sclereids (see Figure 4). Sclereids are thick-walled, heavily lignified cells that are found in the inner bark of trees and are the same colour as the wood. Unlike normal wood fibers, the sclereids are difficult to pulp and therefore remain as fiber bundles that cannot absorb ink, hence the presence of white spots in the printed areas of the sheet. If SEM had not been available, we would not have been able to identify the cause of the problem.

Other analytical techniques that are useful in quality control include surface analytical techniques such as secondary ion mass spectrometry (SIMS), electron spectroscopy for chemical analysis (ESCA), and X-ray photoelectron spectroscopy (XPS). Further details on
Figure 4 SEM image of a sclereid that caused printing problems on a newsprint sheet.

these techniques can be found in the article on surface analysis by XPS (see X-ray Photoelectron Spectroscopy, Paper Surface Analysis by).

6 PROTECTION OF CONSUMERS

Since paper products are used by consumers, it is important to ensure that the products will be safe for the consumer to use. This is especially important for products that will be used in food packaging. The types of compounds that should be monitored in food packaging materials include: (a) compounds that may induce toxicity or allergic reactions, typical examples being halogenated compounds such as dioxins, epichlorohydrin, chloropropanols, solvents and certain dyes; (b) organoleptic substances that may affect the odor and taste of foodstuffs, examples being aldehydes and ketones; and (c) microbiological matter such as Gram-negative bacteria that produce endotoxins.

Regulations of the US Food and Drug Administration (FDA) specify that containers and package components are food additives if they “may reasonably be expected to become a component, or to affect the characteristics, directly or indirectly, of food packaged in the container”. Methods have been developed to determine the migration of components from food packaging papers by use of a specially designed test cell and using solvents (e.g. water, hexane, chloroform and alcohol) that simulate different foods that may come into contact with the papers. The FDA requires that food-packaging papers made from recycled papers be free of optical brighteners.

7 ODORS

Odors in paper and board samples can be a nuisance and their analysis can be difficult. Examples of odors from some common paper products and materials associated with paper are shown in Table 2.

GC techniques are useful in characterizing odors from the paper products. For example, paper can be suspended in water in a jar with a gas-tight lid and then heated at 70°C for 16 h to concentrate the volatiles in the headspace. The headspace gas is then sampled and analyzed by a suitable GC technique. Odor problems in food packaging from a Norwegian mill were attributable to oxidation of lipophilic extractives and degradation of paper additives.

8 ENVIRONMENTAL PROTECTION

Process waters used in the pulp and papermaking process should be purified before discharge into the environment. In a few cases, mills are fully closed, meaning that no effluent waters are discharged. Instead, the process waters are purified by a variety of means and then reused in the pulp and papermaking process. However, the majority of mills do discharge waters into the environment. Such discharges require preparifiction by a combination of chemical and biological treatment systems. Environmental regulations mandate that the waters be monitored for a variety of parameters such as chemical oxygen demand (COD), biological oxygen demand (BOD), total suspended solids (TSS), adsorbable organic halogen (AOX) and resin acids (because of their toxicity to fish). A variety of standard test procedures are available to monitor these parameters (see Pulp and Paper Matrices). Monitoring the amount of resin acids in mill effluents is important because of their toxicity. Typically, the resin acids are extracted by liquid–liquid extraction from effluents, but the requirements for pH adjustment before extraction are still under debate. Some studies report that optimum recoveries are obtained when
extracting samples adjusted to high pH, whereas others report the opposite.

9 ESTROGEN IMICOS

There is an increased interest in the analysis of phytosterols in pulp and paper mill effluents. Phytosterols are estrogen-like compounds that are present in the unsaponifiable fraction of wood resin. The most prevalent are campestanol, stigmasterol, stigmastanol, \( \beta \)-sitosterol, campesterol, and lupeol. These compounds are suspected to be estrogen mimics because their basic chemical structure is similar to that of estrogen hormones. The estrogen mimics are thought to induce low fertility in the male population. For example, Denton et al. and Hunsinger et al. showed that female mosquito fish were masculinized after exposure to plant sterols, whereas Knutson et al. showed that sterols can affect fish reproduction. If they are indeed estrogen mimics, then it is important to ensure that they are absent in mill effluents discharged into receiving waters or in products used by consumers. However, literature data indicate that they are present in mill effluents and pulps. For example, Holmbom and Lehtinen identified lupeol, cycloartenol and methylenecycloartanol in effluent from a Finnish pulp and paper mill; Oikari and Holmbom identified \( \beta \)-sitosterol and betulinol in the final effluent from a European hardwood and softwood bleached kraft mill; and Jansson et al. identified sitosterol, betulin, lupeol, stigmastanol, campesterol, campestanol, methylenecycloartenol, and cycloartenol in elemental chlorine-free and totally chlorine-free acetone extracts of oxygen bleached pulp.

A study of the presence of these estrogen mimics in US mills showed that mill effluent treatment systems removed most of the compounds except for stigmasterol, which appeared to increase in an aerated stabilization basin treatment system. This apparent increase was attributed to other sources of plant sterols such as algae.

Capillary zone electrophoresis (CZE) is one of the novel separation techniques, being applicable, for example, to virtually all important biomass-derived monosaccharides. However, in spite of this fact the utilization of this technique in the pulp and paper industry is currently rather limited. In this chapter practical guidance and some application examples are given to show how carbohydrate material (polysaccharides, oligosaccharides, and neutral and acidic monosaccharides) in pulps and spent liquors can be analyzed by CZE. Emphasis is placed on sample preparation and separation conditions including comparison with other separation methods, such as gas chromatography (GC) and high-performance liquid chromatography (HPLC), generally used for similar purposes. In addition, a short description of other significant degradation products (e.g. aliphatic carboxylic acids and lignin monomers) formed during delignification (e.g. cooking and bleaching) is given. It is concluded that these low-molecular-mass (LMM) degradation products could also be analyzed effectively by CZE.

1 INTRODUCTION

Several techniques have been used to characterize the carbohydrates of chemical pulps and carbohydrate-derived degradation products formed during cooking (present in spent liquors) and bleaching (present in bleaching effluents). Nearly all these carbohydrates originate from cellulose and the main hemicellulose constituents of wood. In addition, minor carbohydrate-containing residues such as arabinogalactans, pectins, and starch can also be regarded as carbohydrate sources.²⁻⁶

Pulp properties are mainly caused by different polysaccharides in pulp. However, carbohydrate-based degradation products (aliphatic carboxylic acids and oligo- and polysaccharide fragments) dissolved in black liquor during kraft delignification have an influence, for example, on the combustion properties of black liquor when it is burnt in the mill’s recovery furnace. Therefore, detailed data on all kinds of carbohydrate-based substances, including their molecular mass distribution, are of great industrial importance.

The wood-based carbohydrates have conventionally been analyzed by various chromatographic systems: GC, HPLC, ion chromatography (IC), or gel permeation chromatography (GPC).²⁻⁶ Capillary electrophoretic systems such as CZE, micellar electrokinetic chromatography (MEKC), capillary gel electrophoresis (CGE), and capillary electrochromatography (CEC) offer the most promising novel techniques for this purpose.¹⁻⁹

In particular, many CZE systems have been developed for the analysis of plant-derived carbohydrates. This is primarily due to the possibility of directly applying these systems, which have high separation efficiency and a short analysis time, to aqueous samples with a relatively wide molecular mass range.

The possibility of analyzing high-molecular-mass (HMM) carbohydrates has so far not been widely used for wood-processing applications. In contrast, most studies related to these applications have concentrated on neutral and acidic monosaccharides and only a few, for example, on oligosaccharides.¹⁰,¹¹ Thus, most
analyses of oligo- and polysaccharides have applied to other feedstocks (e.g. cotton\textsuperscript{(12)} and food\textsuperscript{(13)}) than wood and pulp. However, several substances, such as carboxylic acids\textsuperscript{(14–27)} phenols\textsuperscript{(25,28–30)} and inorganic compounds\textsuperscript{(14,15,17,18,20–27)} also typical of pulp production, can be analyzed, for example, by CZE. Such compounds are discussed in this article only as interfering substances of carbohydrate analyses, with the main emphasis being paid to neutral and acidic carbohydrates.

2 CHEMICAL COMPOSITION OF WOOD

The major chemical constituents of all wood species are the structural substances cellulose, hemicelluloses, and lignin. Other polymeric constituents, present in lesser and often varying quantities, are pectin, starch, and proteins. In addition to these macromolecular components, several nonstructural and mostly LMM compounds (extractives, some water-soluble organics, and inorganics) can be found in small quantities in both softwoods and hardwoods.

Softwoods and hardwoods differ typically from each other with regard to their chemical composition\textsuperscript{(1,31–33)}. In both cases, the cellulose (degree of polymerization (DP) = 10 000–15 000, average molecular mass ($M_w$) 1.6–2.4 x 10\textsuperscript{6} Da) content is more or less the same (40–45% of the wood dry solids), but softwoods usually contain less hemicelluloses (DP = 100–200, $M_w$ = 15 000–20 000 Da) and more lignin ($M_w$ = 15 000–20 000 Da). The typical content of hemicelluloses in temperate-zone softwoods and hardwoods is, respectively, 25–30% and 30–35% of the wood dry solids. The lignin content of softwoods is typically in the range 25–30% of the wood dry solids, whereas the common lignin content of hardwoods varies between 20 and 25% of the wood dry solids. The other compounds (mainly extractives) in woods from temperate zones usually make up about 5% of the wood dry solids, but tropical species often exceed this value. Thus, in woods from temperate zones, the macromolecular substances building up the cell walls account for about 95% of the wood material. In contrast, for tropical woods this value may decrease to an average value of 90%.

It is typical that the structure of hemicelluloses is different between softwoods and hardwoods, whereas cellulose is a uniform component of all woods. Scheme 1 shows the partial chemical structure of cellulose\textsuperscript{(34,35)} and the main hemicellulose constituents\textsuperscript{(36,37)}. In softwoods the primary hemicellulose component is the acetylated galactoglucomannan (glucomannan, 15–20% of the wood dry solids), the nonacetylated arabinoglucuronoxylan (xylan) being a minor constituents (5–10% of the wood dry solids). In contrast, in hardwoods the primary hemicellulose component is the acetylated xylan (20–30% of the wood dry solids) and clearly less nonacetylated glucomannan (less than 5% of the wood dry solids) is present. Arabinogalactan occurs significantly (10–20%) in the heartwood of larches (Larix sibirica/L. decidua), whereas its content in other softwoods is generally less than 1%.\textsuperscript{(1,32)} In addition, different galactans (acidic galactans) are present especially in reaction wood (i.e. compression wood in softwood and tension wood in hardwood)\textsuperscript{(1,32,36,38)}.

The building units of wood carbohydrates are pentoses (D-xylose, L-arabinose, and D-arabinose), hexoses (D-glucose, D-mannose, and D-galactose), and deoxyhexoses (L-rhamnose or 6-deoxy-L-mannose). Small amounts of certain uronic acids (4-O-methyl-D-glucuronic acid, D-galacturonic acid, and D-glucuronic acid) are also present. These units exist mainly as six-membered (pyranose) structures either in the $\alpha$ or $\beta$ forms (Scheme 2).

Lignin is an amorphous polymer with a chemical structure that differs distinctly from the other macromolecular constituents of wood\textsuperscript{(39–41)}. It is also characteristic that, unlike wood carbohydrates, the chemical structure of lignin is irregular in the sense that different structural elements (phenylpropane units) are not linked to each other in any systematic order. However, the close association between lignin and carbohydrate components in wood strongly suggests the existence of a chemical linkage between these constituents forming a lignin–polysaccharide complex (LPC) or a lignin–carbohydrate complex (LCC)\textsuperscript{(1,32)}.

The final organic constituent group – extractives – comprises an extraordinarily large number of diverse substances (i.e. several thousands of individual compounds) mainly with low molecular masses and which by a broad definition are either soluble in neutral organic solvents or water\textsuperscript{(42–44)}. These substances belong to both lipophilic and hydrophilic types and are regarded as nonstructural wood constituents. The ash contents of commercial softwoods and hardwoods are generally in the range 0.3–1.5% of the wood dry solids.

3 DELIGNIFICATION PROCESSES

3.1 General Aspects

Pulping refers to different processes by which wood is converted into a product mass with liberated fibers predominantly used for papermaking\textsuperscript{(1,31,45–48)}. These thermal conversions can be accomplished either chemically or mechanically, or by a combination of these two types of treatment. Thus, with regard to pulping
CARBOHYDRATES FROM CHEMICAL PULPS: CHARACTERIZATION BY CAPILLARY ZONE ELECTROPHORESIS

Scheme 1 Partial chemical structure of cellulose and the main hemicelluloses in softwood and hardwood.

processes, the term “pulp” is used collectively for chemical (yield 45–55% of wood feedstock), semichemical (yield 65–85% of wood feedstock), chemimechanical (yield 80–90% of wood feedstock), and mechanical (yield 91–98% of wood feedstock) pulps. Chemical pulping accounts for about 70% of the total worldwide production, and nowadays about 80% of chemical pulp is produced by the dominant kraft (sulfate) process. The importance of sulfite pulping has clearly decreased during recent decades. All the main chemical constituents (cellulose, hemicelluloses, lignin, and extractives) of wood feedstocks behave differently during wood processing, resulting in differences in the chemical composition of pulp products and waste liquors.

A general goal in cooking prior to bleaching is to obtain as low a kappa number (i.e. the residual lignin content of pulp) as possible without deactivating the residual lignin and with no degradation of product quality. Another current trend is the closing of process water circulation, to decrease the wastewater load. Thus, a totally effluent-free (TEF) mill represents the ultimate objective in pulp production. To avoid the corrosion problems caused by chlorine-containing compounds, oxygen-based chemicals (oxygen, ozone, hydrogen peroxide, and peracids) are used in the totally chlorine-free (TCF) bleaching process. The proportion of elemental chlorine-free (ECF; i.e. the use of chlorine dioxide and hypochlorite, but not chlorine) bleached pulps is gradually increasing worldwide, being about 50% today, whereas the corresponding TCF production is about 6%.

The aim of this section is to give an overview of delignification-based compounds that could be analyzed...
by different CZE techniques. However, only a few such applications have been reported.

3.2 Kraft and Sulfite Pulping

During kraft pulping, or generally during the conditions prevailing at alkaline pulping, roughly half of the wood substance is degraded and dissolved into the cooking liquor, i.e. the black liquor. The organic matter in the black liquor is composed of the degradation products of lignin and polysaccharides in addition to a minor fraction comprising extractives (Table 1). A substantial part of the hemicelluloses is converted to hydroxy carboxylic acids (Scheme 3). In addition, small amounts of dissolved polysaccharides are not completely degraded and can be found in the final black liquor. Dissolution and degradation of lignin during kraft pulping also produces a complex mixture of breakdown products with wide molecular mass distributions, ranging from simple LMM phenols (Scheme 3) to large macromolecules. Of the charged alkali, 70–75% is required to neutralize the aliphatic carboxylic acids and about 20% is consumed to neutralize the degradation products of lignin.

Figure 1 illustrates the typical material balance of wood organics for the kraft process (including the subsequent oxygen–alkali delignification) and the bleaching sequence overall, which produces kraft pulp with high brightness. As can be seen, approximately 90% of the lignin, 60% of the hemicelluloses, and 15% of the cellulose is dissolved during the cook.

There are several modifications of the sulfite method, designated according to the pH of the cooking liquor and producing pulps. These range from dissolving pulps for chemical end-uses to high-yield neutral

a Mainly hemicelluloses-derived fragments.
b Due to the presence of dead-load inorganics, this mass proportion may be higher in some cases.

in differences in the chemical composition of pulp and spent liquor.

Typical sulfite spent liquors differ from alkaline pulping liquors in many respects, the majority of the organic material originating from lignosulfonates and hemicelluloses (Table 2). In principle, a variety of useful products can be produced from these liquors, but today most of their organic solids are burned with the generation of energy and recovery of the cooking chemicals.

3.3 Oxygen–Alkali Delignification and Bleaching

Oxygen–alkali delignification or simple oxygen delignification is a common process for delignifying unbleached pulps because by this process water pollution can be substantially reduced. One of the most important barriers to extending oxygen delignification is the severe degradation of carbohydrates at higher degrees of delignification leading to inferior mechanical properties of fibers and low pulp yields. Due to this nonselectivity, delignification degree of the kraft pulp from conventional coking is normally in the range 35–50%, if a suitable inhibitor (i.e. a protector against carbohydrate degradation) is added. However, this technique offers the most prominent alternative to chlorination and a suitable way of decreasing the use of chlorine dioxide as well.

The overall composition of the spent liquors from delignification can be characterized by dividing the material into common groups of constituents, because only a minor fraction of the total material constitutes distinctly definable compounds. Table 3 illustrates the

sulfite semichemical (NSSC) grades. The AQ (anthraquinone) alkaline sulfite methods lead generally to kraft-type pulps. All these cooking modifications result

clearly the nature of each process. It should be noted that, although the soluble extractives remain almost unchanged during oxygen delignification, they may be somewhat modified after bleaching.

In general, bleaching can be defined as a multistage chemical process applied to chemical and mechanical pulps to increase their brightness\(^1,32,53,54\). The bleaching reactions of pulp components are highly complex and can result in a wide variety of LMM degradation products. It can be concluded that CZE techniques are useful for analyzing many of these degradation products.
4 SAMPLE PREPARATION

4.1 Neutral and Acidic Monosaccharides

Depending on the samples and the CZE procedures used, different sample pretreatments may be required. In particular, removal of lignin-derived fragments, extractives, carboxylic acids, and inorganic substances may be necessary if, for example, the black liquor is analyzed directly without acid treatment (i.e. by hydrolysis of hemicelluloses). These noncarbohydrate substances can interfere with derivatization, detection, separation of carbohydrates or electrokinetic sample introduction.

Purification of carbohydrate samples can be performed in many different ways. The removal of inorganic substances and carboxylic acids can be accomplished by GPC, or a weakly basic anion exchange resin. Most of the lignin and extractives can be removed by extraction with organic solvents or by solid phase extraction (SPE; C18 or NH2 phase).

4.2 Oligosaccharides and Polysaccharides

Oligo- and polysaccharides are analyzed either directly or after hydrolysis. The same sample purification systems can be also utilized in this case. The three methods that have been reported are sulfuric acid, trifluoroacetic acid (TFA), and enzymatic hydrolysis. Of these methods, enzymatic hydrolysis is the most gentle and specific, although it is the most time-consuming technique. Furthermore, it allows the liberation of different uronic acid side groups of hemicelluloses. Hydrolyzates may also contain different oligomers after enzymatic peeling due to incomplete hydrolysis, and their detailed identification can be difficult because of a lack of commercial model compounds.

The acid hydrolysis methods are usually utilized instead of enzymatic peeling because they are less time-consuming and the reagents are easily available. However, a significant drawback of acid hydrolysis is the loss of uronic acids during treatment. The TFA can be removed after hydrolysis by evaporation, but the sulfuric acid should be neutralized either by an anion exchange resin or by calcium carbonate. In the latter case, however, some epimerization of monosaccharides may occur. An insoluble noncarbohydrate residue formed comprises mainly lignin and can be filtered off after acid treatment.

5 METHODS

5.1 Detection Methods and Limits

The main detection systems in commercial capillary electrophoresis (CE) devices are ultraviolet (UV) or laser-induced fluorescence (LIF) detectors. In addition, a refractive index (RI) detector, a pulse amperometric detector (PAD), and an amperometric detector with constant potential (ADCP) have been used. The use of a mass-sensitive detector (MSD) for carbohydrate analysis is limited because it is difficult to find a buffer solution suitable for both separation and detection.

The main difficulties arise from the poor detection of carbohydrates by UV or LIF, as these compounds do not contain chromophores or fluorophores. In spite of this, carbohydrates have generally been detected directly by UV at 195 nm. The sensitivity of this method is not very good and the detectability of carbohydrates has been improved by an indirect UV or an indirect fluorescence detection method. However, most migrated compounds respond to indirect UV and fluorescence detection due to displacement of the background electrolyte. Therefore, noncarbohydrate-based compounds can interfere with carbohydrate detection in these methods. Table 4 shows the different detection methods with the mass detection limits.

More uncommon detection methods such as PAD, ADCP, and RI have also been used. These are nondiscriminatory techniques and the positive responses originate from, for example, carboxylic acids and aromatic compounds can confuse the peak assignment. It is also possible that strongly alkaline conditions, which are used especially with the amperometric detectors, can lead to epimerization and chemical degradation of carbohydrates. Noncompatibility of the gradient elution techniques is a further drawback of an RI detector. The sensitivity of this detection can be increased by extended light path capillaries or z-type detection cells, but the most common method for improving detectability of carbohydrates is derivatization. This is normally based on reductive amination or condensation reactions. Some common derivatization reagents are listed in Table 4.

Schwaiger et al. have studied optimization of precolumn derivatization by 4-ABN. The high sensitivity in this case was achieved by derivatization of 6% 4-ABN solution for aldoses, ketoses, and uronic acids. A derivatization time of 15 min was sufficient at 90 °C. This study also showed that derivatization improved both sensitivity and resolution, mainly because the derivatized carbohydrates were present only in their open-chain forms.

5.2 Electrolyte Systems

The common buffer systems are based on sodium hydroxide, borate (made from boric acid or borax) or phosphate with the different background electrolytes and organic modifiers. Sodium hydroxide electrolytes have been used especially with ADCP or PAD. The

Advantage is that derivatization can be avoided, because carbohydrates are dissociated under highly alkaline conditions. In addition, detection can be improved to the picomole range by indirect UV, for example with sorbic acid. However, strong alkaline conditions can also induce epimerization and degradation. Borate and diethylamine (DEA) have been used to improve the separation efficiency.

Borate is normally considered as a buffer and sodium hydroxide as a chemical agent for adjusting pH. In the case of the borate buffer, which is the most common electrolyte used in the separation of monosaccharides, the pH is kept at a lower level than in the case of the sodium hydroxide electrolyte. The separation power of the former case is based on the negatively charged carbohydrate–borate complexes and their stability, which depends on the hydroxyl group positions in the carbohydrate structure. The orientation of the vicinal hydroxyl groups at C4/C5 and C3/C4 for arabinose, mannose, and glucose interferes with the mutual separation of these monosaccharides due to their almost equal electrophoretic mobilities. The separation selectivity has been optimized, especially with a high borate concentration (200–500 mM), or with organic electroosmotic modifiers such as hexadimethrine bromide (HDB), acetone, acetonitrile, ethylene glycol, or aliphatic alcohols. In addition, pH adjustment (pH 9.0–10.5) has been used to facilitate separation.

Little attention has been given to other means of separation, mainly because of the drawbacks of the above-mentioned methods. A high borate concentration increases the Joule heating due to the high electric current and there is also a risk of precipitation. The stability of well-prepared 500 mM borate buffer has shown to be good under prolonged storage at the room temperature. The formation of borate crystals can begin if the dissolution of borate into water is reduced, as for example during storage in the refrigerator. In some cases the organic modifiers can affect the buffer stability. However, organic modifiers have been shown to be very useful for changing the electroosmotic properties of borate buffer systems and to significantly shorten the analysis time. Other approaches, such as the use of coated capillaries and voltage or buffer programming, have not reported in conjunction with the analysis of wood-based monosaccharides. Polyacrylamide or polyether coatings have been used but no data on voltage or buffer programming have been given for oligo- and polysaccharide separation systems.

Carbohydrates can also be separated under acidic (pH 2.0–2.5) conditions with a 30–200 mM phosphate buffer. In this case the charge should be introduced...
into the carbohydrate molecule because phosphate is not able to form complexes with carbohydrates and carbohydrates are not dissociated under acidic conditions. Reagents such as ANTS, 2-AP, and 6-AQ are used to introduce the ionogenic function. The separation selectivity of phosphate buffer has been improved by tetrabutylammonium bromide. These buffer systems are mainly used for the separations of oligo- and polysaccharides.

5.4 Interfering Substances

Most samples from chemical pulping contain some interfering substances (Table 5). These substances have been shown to make the peak assignment of carbohydrates more difficult in the nondiscriminated detection systems with sodium hydroxide electrolyte. Different methods can be used to avoid interference by aromatic compounds and carboxylic acids. This is especially important when the carbohydrate composition is determined from samples with difficult matrices such as black liquors or bleaching effluents without acid treatment. In acid hydrolysis and especially in sulfuric acid hydrolysis, lignin material is precipitated and can be removed by filtration or centrifugation. Lignin fragments can also be removed, for example, by SPE, GPC, or by extraction with different organic solvents. Volatile carboxylic acids are evaporated during hydrolysis or sample preparation, but different extraction methods can also be applied. The potential interference of carboxylic acids can be reduced by selecting a suitable derivatization method and detection wavelength.

6 EXAMPLE APPLICATIONS

6.1 Neutral and Acidic Monosaccharides

Several CZE methods that have been developed for separating a wide range of neutral and acidic monosaccharides are also suitable for separating pulp-derived monosaccharides (Table 6). Examples of separated analytes are shown with their migration order and mass detection limits in Table 7. In most cases a borate buffer with different concentrations has been used, but sodium hydroxide solution with or without organic additives has also been applied. Only two of these systems have been directly used for analysis of pulp-derived carbohydrates. Rydlund and Dahlman investigated spruce xylan of TMP after TFA and enzymatic hydrolysis. Neutral and acidic 6-AQ-derivatized monosaccharides were separated within less than 16 min by using 420 mM borate buffer. Ristolainen has analyzed the carbohydrate composition of TCF bleaching effluents by using 500 mM borate buffer (Figure 2). In this investigation, CZE and GC separations were also compared to each other. The results indicated that the relative standard deviations for monosaccharide concentrations of the separately hydrolyzed samples were 1.5–8.7% in the CZE systems, whereas in the GC systems these values varied between 2.9 and 5.6%.

The baseline separation of arabinose, glucose, and mannose has generally been a difficult task in many

investigations. Nguyen et al.\(^{56}\) have expected that a complete separation could not be achieved with borate buffer, even if the concentration was increased to a level of 500 mM (Figure 3). This separation problem was avoided by addition of organic modifiers such as 5% methanol, 5% acetonitrile, and 0.001% HDB into the 350 mM borate buffer. The additives changed the direction of the electroosmotic flow and the separation was made by the so-called co-electroosmotic techniques. This kind of procedure markably shortened the total analysis time. Ristolainen\(^{11}\) has recently demonstrated the complete baseline separation with 500 mM borate buffer without organic modifiers. In this case, however, the analysis time was much longer and especially the peaks of acidic monosaccharides were much wider than those detected in the case of the co-electroosmotic system. Voltage programming was not used; the migration time of galactose and acidic monosaccharides could be significantly shortened using this approach.\(^{68}\)

### 6.2 Oligosaccharides and Polysaccharides

The development of CZE separation systems for wood-based oligo- and polysaccharides has been surprisingly...

Analysis of Carbohydrate-derived Constituents after Acid Hydrolysis by Capillary Zone Electrophoresis’, J. Chromatogr. A, 832, 203–209, Copyright (1999), with permission of Elsevier Science.)

7 QUALITY CONTROL

Good laboratory practice is essential in order to obtain reliable results. This section highlights a few important guidelines and recommendations.

7.1 Data Quality Objectives

The correct peak assignments should be confirmed by model and reference compounds, but the detection limits and the linear response range should also be determined. The use of reference compounds in CZE separations is more critical than in many other separation systems to ensure the correct peak interpretation. In addition, the purity of peaks in the actual sample should be monitored, for example by UV or mass spectroscopy spectra; small changes in the separation conditions may give hints in many cases if there exist possible separation difficulties. It is also a good practice to collect temperature, voltage, current, and pressure profiles during runs to ensure a proper repeatability of the results. Changes in these parameters normally indicates possible difficulties, with
the separation facilitating the rejection of nonvalid results.

7.2 Laboratory Operations
Chemically pure reagents and well-prepared, filtered, and properly stored electrolyte or buffer solutions are important for a good separation. In addition, degassing of the buffer is recommended to avoid the formation of bubbles in the capillary and especially in the z-type detection cells. The solution level of the buffer and sample vials should be equal and they must be filtered. Otherwise, the reproducibility is affected by siphoning or the presence undissolved particles.

7.3 Instrument Performance
Some CE devices are equipped with an option that automatically replaces and adjusts the equal solution level in the buffer reservoirs after each run. This replenishment option has been shown to improve the quality of the separation and reproducibility. Unfortunately, there is a high risk that the strong borate buffer will block this system due to crystallization. Therefore, rinsing with water is recommended after each sequence.

A new fused-silica capillary is rinsed with dilute sodium hydroxide solution followed by water and buffer. The same procedure is also used to regenerate the capillary after each run. It is debatable whether this should be done with the running buffer, especially in the case of an acidic buffer. It is therefore good practice to test which method gives the best reproducibility.

Monitoring of the current is advisable because it indicates the condition of buffer, capillary, and electrodes. In particular, it is a good indicator of problems in the CZE systems, where highly concentrated borate buffer...
or sodium hydroxide solutions can crystallize between capillary and electrode, forming a current leak. Changes in the current may also be due to the formation of bubbles or obstructions within the capillary, or to temperature and voltage fluctuations and, in some cases, adsorption of compounds on to the capillary wall. Sodium hydroxide also has a tendency to dissolve the fragile fused-silica capillary. However, many of these problems can be avoided if the capillary is replaced frequently enough, well-prepared solutions are used, and the CZE device is serviced weekly.

8 COMPARISON WITH OTHER SEPARATION METHODS

Conventional methods for determining carbohydrates utilize GC and HPLC. Although GC provides high sensitivity and separation efficiency for monosaccharides, it is not a good approach for determining oligo- or polysaccharides. In general, it has two major drawbacks: first, the presence of multiple peaks, due to the existing equilibrium between different ring forms of monosaccharides including the simultaneous formation of α- and β-anomers; and second, the low volatility of monosaccharides. However, the volatility of monosaccharides can be increased by derivatization using direct silylation or acetylation after reduction to alditols. The problem of multiple peaks can also be avoided by the latter method. A flame ionization detector (FID) is suitable for the most purposes with a detection limit of about 5 ng. However, an electron capture detector (ECD) with halogenated derivatives can be used if a more sensitive detection is needed. In this case, the sensitivity is 100–1000-fold compared to that of FID.

In HPLC or IC techniques as well in CZE systems the isomeric nature of monosaccharides does not present a major problem because mutarotation is so fast that the different forms are able to elute as a single, although somewhat wider, peak. The sensitivity of HPLC or IC is better than that of CZE but, in the former approaches, the limiting factor is a moderate separation efficiency. However, third-generation latex-agglomerated anion exchangers have shown the ability to resolve wood-based monosaccharides without derivatization. The limited stability of these anion exchangers to organic solvents is one drawback that prevents effective removal of organic contaminants. Therefore, the difficult matrices of wood-based carbohydrates may affect the performance of the anion exchange column without sample clean-up. The CZE systems have a high separation efficiency and are capable of simultaneously resolving mono- and oligosaccharides. In addition, the amount of mobile phase needed in CE analysis is much less than that needed in the IC or HPLC techniques. One major drawback of the CZE approach is the need to perform a sample clean-up and to derivatize the analytes, both of which are time-consuming and may affect the quantitative recovery of preparations.

Fourier transform infrared spectroscopy (FTIRS) is the combined use of infrared (IR) light, for illuminating a light-absorbing sample, with an interferometer, for producing an interference pattern from which an absorption spectrum characteristic of the sample is recovered through Fourier transformation. The majority of current IR pulp and paper applications involve the routine characterization of samples that contain variable amounts of water, a very strong IR absorber. Consequently, qualitative IR analysis of pulp and paper samples is best performed with a Fourier transform infrared (FTIR) spectrometer because of the larger optical throughput offered by an interferometer over a dispersive spectrometer. Also, an interferometer simultaneously records all IR frequencies present in the spectrum. These two advantages enable one to acquire high-quality spectra in a few minutes or less. Additionally, since an interferometer accurately determines IR frequencies with the output of a visible-light laser, quantitative determinations which use multivariate calibration methods such as partial least squares (PLS) are much less prone to instrument drift, and hence more accurate. Liquid and solid samples can be analyzed either neat or suitably diluted in a nonabsorbing matrix, through a variety of sampling techniques such as transmission, diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS), attenuated total reflectance (ATR), IR microscopy, and photo-acoustic spectrometry (PAS). Detection limits for quantitative methods vary from 0.01 to 1 percent, depending on the sampling method and the complexity of a sample matrix. However, FTIR spectrometry cannot resolve more than a few components at a time in liquid and solid samples because of the presence of strongly overlapping bands. Therefore, FTIR spectroscopy must often be used in combination with separation techniques such as gas chromatography (GC) or solid-phase extraction (SPE), especially when a complete analysis of the sample is required.
1 INTRODUCTION

Griffiths and de Haseth describe in detail the theory, practice and historical development of FTIRS. Early industrial applications were presented in a series of monographs edited by Ferraro and Basile. Practical aspects of FTIRS are discussed in Ferraro and Krishnan. Jones gives an overview of the subject.

1.1 Definition of Fourier Transform Infrared Spectroscopy and Related Acronyms

FTIRS is a technique that measures the frequency dependence of the interaction of radiation with matter. FTIRS is the combined use of IR light, for illuminating a light-absorbing sample, with an interferometer, for producing an interference pattern from which an absorption spectrum characteristic of the sample is recovered through Fourier transformation. In FTIRS, the selection rules governing band assignments are the same as those found for dispersive IR spectroscopy. However, the greater energy throughput of a FTIR spectrometer, as well as the multiple-scan capability and higher resolution which can be achieved with computing technology, have made possible the use of IR spectroscopy in much lower energy sampling situations than was hitherto possible with a dispersive instrument. The majority of IR spectrometers now use a Michelson interferometer (Figure 1) to produce the interference pattern. Referring to Figure 1, a collimated cylindrical beam emanating from an IR light source is split in half by a beamsplitter. One half of the beam is reflected from a fixed mirror, and the other half from a moving mirror. Both halves recombine and give rise to the interference pattern. Unlike a dispersive instrument where the light interacting with the sample has a narrowly defined frequency, the interference pattern contains light having a wide range of frequencies covering either the near-infrared (NIR) or the mid-infrared (Mid-IR) region of the electromagnetic spectrum. Since the sample absorbs only at certain frequencies, the shape of the interference pattern, or interferogram, changes upon interacting with the sample, thereby producing a spectrum characteristic of the sample. The signal is transformed into an electrical signal by either a deuterated triglycine sulfate (DTGS) or a mercury cadmium telluride (MCT) detector. An array processor then manipulates the data. The spectrum is then obtained by performing a fast Fourier transform (FFT) with the Cooley–Tukey algorithm. A computer controls the interferometer, accumulates, stores and manipulates interferogram data, performs the Fourier transformation, as well as post-spectral manipulation such as plotting, calibration and correlation. Manipulation of interferogram data consists of co-adding successive scans, apodization and phase correction. The first operation improves the signal-to-noise ratio of a spectrum, whereas the latter two remove instrumental artifacts.

1.2 Summary of Advantages and Limitations

IR analysis of pulp and paper samples is best performed with a FTIR spectrometer because of the two major advantages offered by an interferometer over a dispersive spectrometer. These advantages are quite distinct from each other, and are discussed in detail elsewhere.

The first advantage is called the throughput or Jacquinot’s advantage, and results in an optical throughput which is about 200 times larger in an interferometer than that found in a dispersive spectrometer. Thus, a much larger amount of radiation is admitted thought the aperture of an interferometer than through the narrow slit of a dispersive-instrument monochromator.

The throughput advantage is reinforced by the interferometer’s ability to use the entirety of the light signal by simultaneously observing all available frequencies in the spectral region being observed, thereby improving its signal-to-noise ratio by a factor proportional to the square root of the number of available frequencies. The light signal is then resolved into individual frequencies by using the Fourier transformation. This second advantage is called the multiplex or Fellgett’s advantage, and enables one to acquire a high-quality spectrum in a few minutes or less by co-adding a large number of scans. In the Mid-IR, the multiplex advantage varies from a factor of about 16 for a resolution of 16 cm\(^{-1}\) to a value of 64 for 1 cm\(^{-1}\).

The combination of the multiplex and throughput advantages produces a large linear dynamic range, thereby making FTIRS very suitable for quantitative work.
Finally, since an interferometer accurately determines IR frequencies with the output of a visible-light laser, quantitative determinations which use multivariate calibration methods such as PLS are much less prone to instrument drift, and hence more accurate. The increased accuracy is referred to as the laser-reference or Connes’ advantage, and is important when one wants to avoid problems of peak broadening and/or peak shifting during signal averaging. Subtle spectral features are therefore preserved and the level of spectral noise is lower, thereby improving the quality of calibrations. Although this little-known advantage is not as important as the first two, the frequency accuracy which is routinely achievable with FTIR spectrometers is much higher in practice than that available with dispersive instrumentation, especially when using short-wavelength radiation in the NIR region of the spectrum.

The main practical advantage of FTIRS is that liquid and solid samples can be analyzed with little preparation through a variety of sampling techniques such as transmission, DRIFTS, ATR, IR microscopy, and PAS. ATR is also known as multiple internal reflectance (MIR). Detection limits for FTIR quantitative methods vary from 0.01 to 1 percent, depending on the sampling method and the complexity of a sample matrix. The main disadvantage of FTIRS is that it cannot resolve more than a few components at a time in liquid and solid samples because of the presence of strongly overlapping bands. Therefore, FTIRS must often be used in combination with separation techniques such as GC or SPE, especially when a complete analysis of the sample is required.

1.3 Definition and Use of the Mid- and Near-infrared Regions

The frequency range used for routine pulp and paper applications normally extends from 400 to 14,000 cm\(^{-1}\), and covers both the Mid-IR and NIR ranges. The presence of very strongly absorbing fundamental absorption bands in the Mid-IR region (400 to 4000 cm\(^{-1}\)) dictates the use of sampling techniques with a very small effective path length which minimize the extent of these absorption bands, such as ATR and DRIFTS. These sampling techniques are particularly effective when water is present in a sample. On the other hand, in the NIR region (4000 to 14,000 cm\(^{-1}\)) the majority of studies have been performed with cheaper dispersive instrumentation, which have sufficient throughput for most routine applications.

1.4 Topical Overview of Article

A brief historical survey of the development of early dispersive IR spectroscopy applications in the pulp and paper industry will first be presented, followed by an overview of the most useful FTIR sampling methods and calibration techniques. Representative laboratory and on-line applications will be demonstrated. Data quality problems frequently encountered with pulp and paper samples will then be diagnosed, and remedies will be suggested. Next, selected examples relating to the development of quantitative methods will be given. Finally, FTIRS will be compared to other spectroscopic techniques, such as Raman and NIR spectroscopy.

2 HISTORY

2.1 Traditional Pulp and Paper Applications of Infrared Spectroscopy

Chemists have been using IR spectroscopy for nearly fifty years to characterize lignocellulosic samples. Prior to the 1980s, these studies were performed with dispersive instrumentation, which used either a grating or a prism. Data acquisition was slow and cumbersome, and relied on analog technology to record data. Nevertheless, the scope of solid-phase applications that were then pioneered is just as broad as that of current research.

For example, lignin [9005-53-2] variations between different softwood species were characterized.\(^7\) The groundwood content of paper was measured by calculating the ratio of the lignin peak to that of cellulose [9004-34-6].\(^8\) Similarly, the kappa number of pulps was determined by using MIR and a cellulose peak as an internal standard.\(^9\) The photo-degradation of cellulose was reported to be a surface effect\(^10\) and to be correlated to an increase in the amount of carboxyl or carboxyl groups, as evidenced by the appearance of a band at 1740 cm\(^{-1}\). Lipids in beech bark were investigated.\(^11\) The total hydroxyl content of cellulose esters was determined by NIR.\(^12\) Kraft pulping process gases were analyzed by IR spectroscopy.\(^13\) It was concluded that, because of the cumbersome sample preparation and transport problems then associated with IR analysis, coulometric titration or GC was better suited for mill use.

2.2 Modern Development of Fourier Transform Infrared Spectroscopy

Griffiths and de Haseth have briefly discussed the historical development of FTIRS.\(^1\) IR spectroscopy underwent a period of partial eclipse during the 1960s and early 1970s because of the rapid growth of other structural determination techniques such as nuclear magnetic resonance (NMR) and mass spectrometry (MS), as well as the development of separation techniques such as gas and liquid chromatography. MS and gas and liquid chromatography thus replaced IR spectroscopy as the
method of choice in performing quantitative analysis. Also, the lack of versatility of sampling methods other than transmission, tedious preparation protocols and the need to scrupulously dry samples precluded the use of IR spectroscopy in many industrial applications.

Even though physicists developed interferometers at the turn of the century, these instruments were of little use to chemists until gas lasers and minicomputers became available in the late 1960s. The minicomputer allowed spectral computation to be done in real time. The helium–neon (He–Ne) laser made possible the monitoring of the travel of the moving mirror, and permitted the interferogram to be digitized at precisely equal intervals, thereby creating an internal wavelength standard.(1) In the late 1970s, the rapid commercialization of FTIR spectrometers spurred the development of new IR sampling techniques such as DRIFTS, ATR, FTIR microscopy and PAS, all of which took advantage of the greater throughput available with interferometers. Computational software packages, which calculated the FFT immediately after acquiring the data, also became available. Additionally, these packages performed post-spectral processing of the mass of digital data now available. FTIR instrumentation thus became more user-friendly, and hence more attractive for pulp and paper scientists. In the mid-eighties, FTIR spectrometers began to be used in the pulp and paper industry. By the mid-nineties, a wide range of applications had been developed, most notably in the fields of contaminant analysis and pulp manufacture process control. FTIRS is now used for routine analysis in most pulp and paper laboratories around the world and, increasingly, for process control applications in mill environments.

2.3 Early Fourier Transform Infrared Spectroscopy

Applications to Pulp and Paper Problems

In the late 1980s, the first pulp and paper applications of FTIRS appeared in the literature. For example, a method was developed with the use of DRIFTS(14) for estimating lignin in unbleached pulps. The method is based on a linear correlation between the area of the 1510 cm⁻¹ IR band and kappa number. The relationship holds for a range of hardwood and softwood pulps having kappa numbers ranging from 10 to 120. In another application, an ATR method for controlling the cooking degree of pulp during pulp digestion was described.(15) The method analyzes the composition of the cooking liquors before and during the cook, and uses correlations of either peak heights or peak integrals between 1400 and 1550 cm⁻¹ with kappa numbers. Finally, pulp and paper samples were examined by IR microscopy.(16) The utility of the technique for identifying deposits, laminates and surface coatings was demonstrated.

2.4 Current Scope of Pulp and Paper Applications of Fourier Transform Infrared Spectroscopy

FTIRS is now used in various ways in the pulp and paper industry, especially for laboratory bulk analysis of condensed-phase samples that are difficult to analyze by any other method. Important applications include the characterization of lignocellulosic materials such as pulp and lignin samples, papermaking additives, extractive and contaminant analysis, and process control. The technique is particularly useful for the in situ analysis of contaminants that are difficult to extract from their matrix. FTIRS is also best applied whenever high sensitivity and/or speed is needed, such as in the analysis of pulping liquors, demanding quantitative determinations, as well as process and quality control applications.

3 SAMPLING METHODS AND CALIBRATION TECHNIQUES

The purpose of this section is to briefly review the most important sampling methods and calibration techniques that are currently available to a person interested in using IR spectroscopy to pursue the determination and/or characterization of pulp and paper-related samples. This review is not meant to be exhaustive; the relative emphasis given to each sampling method reflects the degree of use of that method in the pulp and paper industry. For example, gas analysis, which has seen little activity in recent years, will not be discussed. The reader is referred for more details to the reviews on sampling methods by Krishnan and Ferraro,(17) Friese and Banerjee,(18) Faix,(19) and to the monograph by Griffiths and de Haseth.(1) Haaland(20) has extensively reviewed univariate and multivariate calibration methods.

3.1 Sampling Methods

A variety of methods is available for sample determination by IR spectroscopy. The nature of the sample, the goals of the analysis and the time available dictate the choice. The vast majority of IR pulp and paper applications used to be done with transmission cells. Elimination of all traces of water is critical in obtaining good-quality spectra. In the transmission method, Beer’s law (Equation 1) expresses the intensity of IR radiation traversing a sample:

\[ I = I_0 \times 10^{-acL} \]  

(1)

where \( I_0 \) is the intensity of the source, \( I \) is the intensity of the transmitted radiation, \( a \) is the absorption coefficient, \( c \) is the concentration of the absorbing species and \( L \) is the optical path length of the radiation in the sample. Spectra
are customarily presented either as absorbance, $A$, or transmittance, $T$, which, by rearranging Equation (1), are defined by Equation (2):

$$ T = \frac{I}{I_o} = 10^{-ac}T = \log_{10} \frac{I}{I_o} = acl $$

Thus the absorbance is linearly proportional to the concentration of the absorbing component. The linear relationship between $A$ and $c$ expressed by Equation (2) is the conceptual basis for the calibration methods used in IR spectrometry, such as PLS. Other than the well-known transmission method, the most widely used IR sampling methods for pulp and paper applications are DRIFTS, ATR, IR microscopy and, to a much lesser extent, PAS. These methods will now be briefly reviewed. The advantages and drawbacks of each method will also be discussed in a pulp and paper industry context.

3.1.1 Diffuse Reflectance Infrared Fourier Transform Spectroscopy

The technique of diffuse reflectance predates the advent of FTIR spectrometers, but did not gain wide acceptance until an accessory with efficient collection optics was designed in the late 1970s. Referring to Figure 2, the light from the source is collected by a flat-mirror system (3), reflected onto a large hemiellipsoidal mirror (2), which then focuses it on the sample (1). The sample usually consists of a small amount of powdered sample which has been diluted in a highly reflective, nonabsorbing matrix such as powdered potassium chloride [7447-40-7].

As shown in Figure 3, IR light having an intensity $I_o$ is partly reflected ($I_s$) through specular reflectance from the sample surface and partly transmitted to a depth of a few micrometers, where it is either completely absorbed by the sample or scattered ($I_d$) back to the surface. This process is repeated a few times until some of the light is re-emitted ($I_r$) at the surface in all directions. The re-emitted light is thus diffuse, and contains spectral features characteristic of the sample. This light is then collected by a second hemiellipsoidal mirror and sent to the detector by a second series of flat mirrors similar to the first.

The reflectance data can be converted to a transmission-like spectrum by using the Kubelka–Munk model. This model relates the reflectance to the absorption coefficient, $a$, found in Beer's law according to Equation (3):

$$ \frac{2.303 ac}{s} = \frac{(1 - R_\infty)^2}{2R_\infty} $$

where $c$ is the concentration of the absorbing species, $s$ is the scattering coefficient of the sample, and $R_\infty$ is the reflectance of an infinitely thick sample, as determined relative to a nonabsorbing standard. Since dilution renders the scattering coefficient, $s$, nearly independent of sample absorption, the right-hand side of Equation (3) is now proportional to $ac$, and the spectrum of a diluted sample will resemble that of a transmission spectrum.

The main advantage of using DRIFTS is that minimal sample preparation is needed. DRIFTS is an easy means of obtaining the IR spectra of solids such as lignin and cellulose which are difficult to study with the transmittance method. It is very difficult to grind such materials into fine, uniform powders, but DRIFTS can be performed with coarsely ground materials. For example, samples as small as 0.25 mm can be analyzed as received. With larger samples, one must scrape a very small amount of sample off the surface of the object to be analyzed, grind one part of sample into a powder with 20 to 50 parts of KCl, and put the mixture into a sample cup. Even liquid extracts of

---

Figure 3 A diagram of the path taken by the radiation during DRIFTS sampling. (Reproduced by permission from M.A. Friese, S. Banerjee, in Surface Analysis of Paper, eds. T.E. Conners, S. Banerjee, 119–141 Copyright CRC Press, Boca Raton, Florida © 1995.)
either dissolved of suspended solids can be analyzed with the use of a solvent elimination technique:\textsuperscript{[22]} one simply presses freshly ground KCl into the sample cup, put a drop of the extract onto the KCl, and let the volatile solvent evaporates. Transmission-like spectra are obtained. All components present in sufficient quantities will be detected: strong IR absorbers such as esters and acids can be detected in sub-micrometer quantities. The DRIFTS method is particularly useful when it is used in combination with a user-developed spectral library customized for the types of samples and contaminants commonly found at a particular mill. One can identify unknown samples by searching the spectral library.

Specular reflectance is produced by mirror-like surfaces, and distorts DRIFTS spectra. Even though DRIFTS accessories are now designed to remove most of the specular reflectance, the presence of inverted peaks produced by residual specular reflectance is the main disadvantage of this technique. Specular reflectance can be partially removed by increasing the dilution of the sample. However, if the major component of the sample is affected strongly by specular reflectance, further dilution of the sample will wash out the spectral features of the minor components, which defeats the purpose of the analysis. DRIFTS is mainly a qualitative tool and, even though it is possible to develop quantitative methods with multivariate calibration, is less amenable to quantitative determination than the transmission method. Accessories are available from a wide variety of suppliers.

3.1.2 Attenuated Total Reflectance

ATR, which was introduced in the 1960s, successfully addressed the problem posed by highly absorbing samples.\textsuperscript{[23]} ATR is a technique for analyzing films, powders, pastes and liquids with the aid of an internal reflection accessory, and is ideal for studying the surface composition of films or coatings, and for determining the concentration of dissolved components in aqueous solutions. As an alternative to the transmission method, this technique is especially useful when components such as water with high extinction coefficients absorb so strongly that their absorbance is no longer linear. Referring to Figure 4, IR radiation from the source is made to propagate at an angle through a reflecting rod. This rod is made of an IR-transparent material with a high index of refraction, $n_1$, such as zinc selenide [1315-09-9], zinc sulfide [1314-98-3] or germanium [7440-56-4], which is surrounded by a solid or liquid sample with a lower index of refraction $n_2$. When this radiation strikes the internal surface of the high-index material, the incident beam splits into a refracted part and a reflected part. Let $\theta$ be the angle of incidence as defined from a line perpendicular to the internal surface of the reflecting material. If the angle of incidence is greater than a critical value $\theta_c$, no refraction occurs and the beam is totally reflected back into the high-index material. The reflected ray will have nevertheless propagated for a very short distance called the penetration depth, $d_p$, into the sample and returned to the reflecting material, after having been slightly absorbed by the surrounding sample. The reflected ray is thus attenuated, and provides structural and quantitative information about the chemical components present in the sample. This process is repeated a number of times, $N_r$, along the reflecting medium before the radiation reaches the detector. The effective path length, $l$, is thus $N_r$ times the penetration depth, $d_p$, and is given by Equation (4):\textsuperscript{[23]}

\begin{equation}
    l = N_r d_p = \frac{N_r \lambda}{2\pi (n_1^2 \sin^2 \theta - n_2^2)^{1/2}}
\end{equation}

where $\lambda$ is the wavelength of the IR radiation in air. Since the penetration depth usually falls between 0.05 $\lambda$ and 0.2 $\lambda$, the effective path length $l$ can vary from 0.25 to 4 $\mu$m, depending on the wavelength and reflecting material.\textsuperscript{[17]} Thus, $l$ is very small in comparison with other FTIR sampling techniques, even though it increases ten times from 4000 to 400 cm$^{-1}$. For archival purposes, an ATR spectrum can be converted to a transmission-like spectrum by using Equation (3). The converted spectrum will then exhibit undistorted features.

The main advantage of this sampling technique is the ability to study bulk samples that contain strongly absorbing species such as water. The absorbance of dissolved species can therefore be measured against that of water without saturating the detector. Another advantage is the capacity to perform surface analysis. Finally, this technique requires minimal sample preparation.

A major drawback of this sampling technique is that the surface of many reflecting rods is fragile and easily attacked by harsh chemicals. Many reflecting-rod surfaces exhibit a tendency to foul or etch over time, even if
one tries to minimize long-term exposure to process liquors. Calcium scale deposits are especially hard to clean, and particular care must be taken by the analyst to avoid damaging the surface: a mildly acidic solution is recommended. Consequently, reflecting rods must be re-polished periodically; as a result, there is a slight increase in total effective path length after each re-polishing operation. For laboratory applications, this represents a small problem: calibrations used in the laboratory can be adapted so as to account for this gradual change. In process applications, however, the choice of optical-element material must be carefully considered so that the sampling system can be designed so as to minimize lengthy exposure of the material to the process environment, thereby maximizing its lifetime. A slip-stream sampling configuration is an excellent way of achieving this objective. Reflecting rods and accessories are available from a wide range of vendors in either rectangular cross-section configurations for laboratory liquid and solid sampling, or in cylindrical cross-section configurations for process monitoring of liquid streams.

3.1.3 Fourier Transform Infrared Microscopy

When the sample to be analyzed is smaller than 0.25 mm, the use of a FTIR microscope is required. A schematic of a FTIR microscope is shown in Figure 5. This specially designed apparatus must focus the IR beam from the spectrometer onto the sample, collect the IR radiation that has interacted with the sample, deliver it to a detector, and allow the user to view and define the area to be analyzed. The microscope thus must have identical geometric configurations for the IR and visible beams. This requirement is accomplished through the use of Cassegrainian optics. Visual inspection of the sample is done with the microscope, a spot is selected, and the IR beam is then focused on the sample by a Cassegrain mirror condenser. The transmitted/reflected IR radiation is then collected with a Cassegrain mirror objective and sent to a liquid nitrogen-cooled MCT detector. The spatial resolution is approximately between 4 and 30 µm in the Mid-IR range. The practical range of sample sizes is from 20 to 30 µm. FTIR microspectroscopy and its application to paper samples are described in detail by Sommer et al.\(^{24}\) Practical aspects of FTIR microscopy are also discussed in Humecki.\(^{25}\)

The main advantage of this technique is its ability to analyze very small samples, down to one pulp fiber diameter. However, unlike visible microscopy, this technique cannot resolve lignocellulosic structures found within the fiber wall, which are of the same size as the incident radiation and below the diffraction limit (10 µm). Another drawback is the need to maintain the detector at liquid nitrogen temperatures for greater sensitivity, if it is not being thermo-electrically cooled. Finally, the cost of a FTIR microscope is roughly the same as that of a stand-alone FTIR spectrometer, thereby doubling the effective cost of FTIR microscopy, compared to other sampling methods.

3.1.4 Photo-acoustic Spectrometry

Fourier transform PAS is a method whereby the sample is irradiated in a closed cell with light whose intensity is modulated by a rapid-scanning Fourier transform spectrometer. The modulation frequency is proportional to the IR frequency, and goes from 125 to 1250 Hz for a DTGS-equipped FTIR spectrometer with a mirror velocity of 0.16 cm s\(^{-1}\). The intensity of the light penetrating into the sample falls off exponentially with depth, with a decay constant of \(1/(ac)\), where \(ac\) is the absorptivity coefficient from Beer’s law. As shown in Figure 6, the absorption of radiation by the sample causes the temperature of the sample to rise. The modulated heat diffuses to the surface and is then transferred from the sample surface to an IR-transparent gas with good thermal properties such as helium [7440-59-7]. This produces a modulated heating and pressurizing of the gas inside the cell, which is then picked up as sound waves by a microphone. The strength of the signal is proportional to the value of \(ac\) and inversely proportional to the square
The root of the modulation frequency. The PAS signal is thus about three times weaker at 4000 cm\(^{-1}\) than that at 400 cm\(^{-1}\). Even so, the resulting spectrum is very similar to an absorbance spectrum. Penetration depths vary from a few micrometers to a few tens of micrometers, and can be adjusted by changing the modulation frequency. Since there is no wavelength range, one detector can be used from the ultraviolet (UV) to the far IR.

The main advantage of PAS is that one can obtain spectra on any type of opaque solid or semi-solid material. In addition, the PAS signal is produced only at those frequencies where absorption by the sample occurs, with little or no interference from scattered radiation. It is especially useful for minerals that exhibit strong specular reflectance such as talc [14807-96-6], alum [7784-24-9] and calcium carbonate [471-34-1]. PAS is thus another technique that has benefited from the advent of FTIR spectrometers.

Unfortunately, after an initial surge in interest regarding the study of wood samples,\(^{26}\) this technique has been recently eclipsed by DRIFTS, mainly because one can now acquire DRIFTS spectra of wood samples which are virtually free of specular reflectance with the accessories now available on the market. Also, the absolute PAS signal cannot be used directly for quantitative analysis: one must use internal standards and peak ratios. Finally, commercial PAS accessories are not as widely available as they were a few years ago.

Table 1 summarizes the advantages and drawbacks of each sampling method, the kind of samples that can be analyzed with the method, along with an estimate of the concentration range over which the method gives optimal results.

### 3.2 Calibration Methods

In the recent past, one had to isolate a spectral band in order to perform IR quantitative analysis. Nowadays, the ability to use the entire spectral range has greatly extended the range of samples that can now be quantitatively analyzed by IR spectroscopy. Indeed, the IR spectrum of samples can also be used for the determination of the chemical and physical properties of individual chemical components in the sample.\(^{29}\) An illustration of the power of multivariate calibrations over univariate determinations is given in Figure 7. Figure 7(a) shows how an impurity may affect the spectrum of the species being determined. In Figure 7(b) we see that, in the presence of that impurity, the real absorbance reading, \(A_t\), at a frequency \(v_1\) is overstated by the error \((A_m - A_t)\), but nevertheless falls on the calibration curve. Thus, it is impossible to tell whether \(c_m\) or \(c_t\) constitutes the real value. On the other hand, if a second frequency \(v_2\) is used, the impurity will be detected Figure 7(c) as an outlier to be treated with suspicion.

The main advantages of multivariate methods over univariate methods are that:

IRE, internal reflection element.
In this section, we give a brief description of two different, but related, multivariate calibration methods: classical least squares (CLS) and PLS. We also provide a summary of their respective advantages and drawbacks.

For a description of calibration methods such as inverse least squares (ILS), principal component analysis (PCA) and principal component regression (PCR), the reader is referred to the review written by Haaland20 and to a detailed discussion by Haaland and Thomas.27

3.2.1 Classical Least Squares Calibration

Since the basis of this method is the linear form of Beer's Law as given by Equation (2), this method is easier to grasp than the other multivariate methods, the majority of which are variants of CLS utilizing different models with various assumptions. The general calibration procedure used in CLS is common to all multivariate calibration methods, and consists of two main steps: a calibration step and a prediction step. First, one acquires absorbance readings from the IR spectra of a series of n sample mixtures of all m components known to be present in the unknown samples. That series must span the range of variation of all the factors affecting the spectra of unknown samples. The calibration model is then calculated with the use of matrix algebra, which enables one to solve for each of the i spectral frequencies n simultaneous linear equations in m unknowns. From Equation (2), one sets $D_{\text{al}}$ for a constant path length and obtains Equation (5), for a series of n mixtures, assuming that the absorbance values are additive:

$$ A_{n,i} = \sum_{j=1}^{m} c_{n,j} k_{j,i} + e_{n,i} \quad (5) $$

where $e_{n,i}$ are the residual errors between the least squares fit line and the actual absorbance values. Since these are calibration samples, the concentrations are known and the absorbance values have been measured. Therefore, one obtains m plots of $k_{m,i}$ for all i data points, thereby reconstructing the pure-component spectrum for each of the m components, as shown in the right-hand side of Figure 8. These pure-component spectra can then be used in the prediction phase of the analysis for determining the concentrations of the m components in the unknown sample. A least-squares procedure calculates the best linear combination of pure-component spectra that minimizes the sum of squared differences calculated from the $e_{n,i}$ values found between the actual and calculated spectra.20 A better way of solving simultaneous equations is by using linear algebra. Therefore, rewriting Equation (5) in matrix form and expressing the spectra presented in the absorbance matrix as rows rather than columns, we obtain Equation (6):

$$ A = CK + E_a \quad (6) $$

where $A$ is the $n \times i$ matrix containing the absorbance values of the n samples at i frequencies, $C$ is the $n \times m$ matrix of the $m$ component concentrations in

---

**Figure 7** Advantage of multivariate calibrations over univariate calibrations. The 'X' in (b) and (c) indicates data obtained from a sample containing both the analyte and the impurity. (Reproduced by permission of Academic Press and of the author from D.M. Haaland, in Practical Fourier Transform Infrared Spectroscopy: Industrial and Laboratory Chemical Analysis, eds. J.R. Ferraro, K. Krishnan, Academic Press, San Diego, CA, 395–468 © 1990.)

1. redundant spectral data provide increased precision;
2. baseline variations can be accounted for; and
3. outliers are readily detected.
the $n$ samples, and $K$ constitutes the $m \times i$ matrix of pure-component spectra. $E_a$ is the $n \times i$ matrix showing the spectral noise present in the spectra. The least squares solution for the $K$ matrix in Equation (6) is then Equation (7):

$$K = (C^T C)^{-1} C^T A$$

where $K$ is the least-squares estimate for the $K$ matrix coefficients. Prediction for samples of unknown concentration is straightforward since $K$ can be obtained from Equation (7) and $A$ is calculated from the spectral data. The vector equivalent of Equation (6) is then solved for the concentration.

The advantages of CLS are that it can be used for moderately complex mixtures and that the full spectrum can be used, thereby averaging out spectral noise. However, one must know the concentration of all components. Also, the method assumes that components do not interact. Finally, the calibration is extremely sensitive to baseline and collinearity effects.

### 3.2.2 Partial Least Squares Calibration

Some of the limitations of the CLS calibration can be overcome by using factor analysis methods such as PLS. The latter is a factor analysis method that creates a new coordinate system by generating mixed-component spectra instead of pure-component spectra. This method simultaneously decomposes both the calibration spectra and the concentration data into two basis sets of loading vectors and two sets of scores: one set for the spectral data, and the other for the constituent concentrations. Thus, we have Equations (8) and (9):

$$A = TB + E_a$$

$$C = TV + E_c$$

where $A$ is the $n \times i$ matrix of spectral data ($n$ spectra with $i$ frequencies) expressed as absorbance values. $T$ is the $n \times h$ score (intensity) matrix in the new coordinate system of the $h$ PLS loading vectors for the $n$ sample spectra, whereas $B$ is the $h \times i$ loading-vector matrix of coefficients relating the scores (intensities) of $T$ to the absorbance values. Referring to Equation (9), $C$ is the $n \times m$ matrix of component concentration data ($n$ spectra with $m$ components). $V$ is the $h \times m$ loading-vector matrix of coefficients relating the scores (intensities) of $T$ to the concentrations, whereas $E_c$ is the $n \times m$ matrix of concentration errors not fitted by the model. The rank $h$ is the optimal number ($h < n$; $h < i$) of loading vectors for modeling the calibration spectra in $A$. Equation (9) is similar to that used in the ILS method, whereby concentrations are modeled as a function of absorbance for a number of selected frequencies. Indeed, in a noise-free system, the set of full-spectrum simultaneous linear equations is over-determined and only a small number of frequencies are needed to fully characterize the calibration spectra in $A$. Therefore, the true spectral variation will be concentrated in the first few loading vectors. These loading vectors are linear combinations of the original calibration spectra. The two sets of scores are forcibly related to each other by swapping their contents before the contribution of each factor is removed from the raw data. The vector equivalent of Equation (9) is thus solved one component at a time for each value of $m$. The use of the concentration information during the decomposition process causes spectra containing high component concentrations to be weighted more heavily than low-concentration spectra. PLS thus takes advantage of the correlation that already exists between the spectral data and the component concentrations. Instead of obtaining pure-component spectra as in CLS, one obtains a set of loading vectors that not only model the spectral contribution of each component, but also Beer’s law nonlinearities, chemical interactions, and baseline fluctuations. By contrast, in the CLS calibration model, the factors are constrained to follow Beer’s Law, with one factor per analyte present. The intensities are the

Component concentrations, whereas the loading vectors are the pure-component spectra.

The main advantage of PLS is that it can be used for very complex mixtures since only the concentration of the constituents of interest is required, as opposed to CLS where the concentration of all constituents is required. Another advantage of the PLS calibration method is its ability to overcome collinearity effects. These effects are often seen in spectral data whereby the presence of inter-correlated variables leads to unstable calibrations. PLS is also a full-spectrum method, unlike ILS, so that the spectral noise can be spread out over many frequencies. This type of calibration can sometimes predict samples in the presence of contaminants not present in the original calibration. Thus, the method is particularly useful for pulp and paper applications since samples show considerable band overlap and significant matrix interferences. However, a large number of samples are required for generating an accurate calibration. Table 2 summarizes the advantages and drawbacks of various types of calibration.

4 LABORATORY APPLICATIONS

For a good overview on applications of FTIRS to pulp and paper problems, the reader is referred to the excellent reviews by Banerjee[18] and Faix[19]. In this section, we will cover qualitative applications such as wood species characterization, lignin analysis, determination of extractives and contaminants, as well as the analysis of papermaking additives. A discussion of the development of quantitative methods will be provided in a later section, along with some specific examples.

4.1 Lignocellulosic Material Characterization

4.1.1 Wood Species Classification

Subtle interspecies differences in cellulose, hemicellulose [9034-32-6], lignin, lignocellulose [11132-73-3] and extractive content can be detected through by careful spectroscopic analysis. DRIFTS can be used for differentiating between species of coniferous wood.[28] A small number of frequencies are selected by performing a combination of PCA and correlation. The approach works best for species with high levels of extractives.

4.1.2 Cellulose and Lignin Characterization

Deconvolution can be used for measuring the increase in the degree of crystallinity[29] observed for cellulose I in samples originating from ramie, cotton, sulfate pulp and bacterial cellulose (Figure 9a). The same trend can be observed (Figure 9b) through an increase in the band at 3440 cm⁻¹, with the sequence going from viscose fibers (amorphous) to cellulose crystals. By using DRIFTS and potassium bromide [7758-02-3] (KBr) pellets, one can perform[30] a structural analysis of lignin that relates IR spectral information to several structural features in lignin samples as determined by conventional methods. As shown in Figure 10, good correlations are obtained for the hydrolysis ratio (a), the number of phenolic hydroxyl (b) and methoxy groups (c) per phenyl propane unit. Significantly better results are obtained with the DRIFTS method than with the KBr pellet method because of the latter’s sensitivity to moisture content. One can also monitor the changes that occur in wood during delignification with various pulping agents such as cold sodium chlorite [7758-19-2], caustic soda [1310-73-2], soda-anthraquinone [84-65-1] and neutral sodium sulfite [7757-83-7] with KBr pellets. Changes in fiber oxidation and in the amount of lignin, as well as the degradation of hemicellulose, can easily be detected.[31]

4.1.3 Color/Brightness Reversion Studies

The brightening of mechanical pulp with hydrogen peroxide [7722-84-1] can be studied with the use of PAS.[32] One must select three internal-standard peaks (3400, 1510 and 1056 cm⁻¹). A decrease in peak intensities in the region from 1750–1600 cm⁻¹ is found to correspond
to alkaline deacetylation (1740 cm\(^{-1}\)) and to the net removal of conjugated carbonyl structures (1650 cm\(^{-1}\)). The effect of irradiation wavelength on the color reversion behavior of unbleached and bleached mechanical pulp can be studied.\(^{33}\) As shown in Figure 11, a decrease in the guaiacyl peak for lignin (1507 cm\(^{-1}\)) is observed at shorter irradiation wavelengths, accompanied by a simultaneous increase in carbonyl content (1719 cm\(^{-1}\)). An increase in the peak for conjugated carbonyl groups is also observed at 1678 cm\(^{-1}\) for irradiation frequencies of 390 and 500 nanometers.

4.2 Extractives Analysis

Sitholé\(^{34}\) reviewed analytical methods for the analysis of extractives. The use of FTIRS and NIR spectroscopy were briefly discussed.

4.2.1 Resin and Fatty Acids

The composition of crude tall oil [8002-26-4] can be elucidated with the use of DRIFTS.\(^{35}\) As shown in Figure 12, one obtains a relatively featureless spectrum, except for the carboxyl and acid bands. Nevertheless, characteristic absorption peaks appear at 1720, 1460 and 1278 cm\(^{-1}\). When the analyst is faced with a complex matrix, a sequential extraction scheme must be used in conjunction with FTIRS so as to maximize the benefits of the technology.

4.2.2 Triglycerides

Triglycerides deposited on cotton fabrics\(^{36}\) can be studied with the aid of the ATR sampling technique. The triglycerides originate from artificial body soil, which constitutes a representative mixture of free fatty
acids [61790-12-3], triglycerides, mono- and diglycerides, hydrocarbons and cholesterol [57-88-5]. As shown in Figure 13, pressing the cotton fabric several times against the ATR element results in a steady increase in the triglyceride ester peak at 1750 cm\(^{-1}\). This technique is directly applicable to the study of sterol esters deposited on pulp.

### 4.3 Contaminant Analysis

DRIFTS has proven to be very useful as a method for analyzing plastic, pitch and dirt specks found in the kraft process and on market pulp sheets because of the minimal preparation required. Samples can even be analyzed as received. Here are a few examples.
4.3.1 Stickies/Deposits and Plastics

Recycled fiber being used in pulp and paper mills contains contaminants such as adhesives, hot melts, coating binders, ink residues, de-inking chemicals and wet-strength resins. These contaminants are referred to as 'stickies'. Since these contaminants often contain more than one component, IR identification is often difficult without some form of fractionation. Stickies and deposits can then be analyzed by either DRIFTS or transmission, after sequential extraction with organic solvents such as chloroform [67-66-3], methanol [67-56-1] or acetone [67-64-1]. Detailed descriptions of analytical procedures for sequential extraction are given by Sitholé et al. and Guo and Douek. The extract is then applied directly on an alkali halide salt, and the solvent is made to evaporate prior to analysis. FTIR analysis can even distinguish between fatty acid and resin acid soaps of aluminum and calcium: calcium fatty acid soaps have a characteristic doublet at 1590 and 1540 cm\(^{-1}\), whereas calcium resin acid soaps have absorption peaks at 1549 and 1405 cm\(^{-1}\). Calcium fatty acid soaps have absorption peaks at 1585 and 1435 cm\(^{-1}\).

Indeed, some of these characteristic peaks may sometimes be masked in the spectrum of a deposit sample, but not always. For example, a DRIFTS spectrum of a typical solid soap deposit is shown in Figure 14. The deposit is simply mixed with potassium chloride (KCl) and ground to a powder. The peak characteristic for soap deposits appears at 1550 cm\(^{-1}\), whereas their resin-acid counterparts only absorb strongly at 1585 and 1435 cm\(^{-1}\).

Figure 15 FTIR spectra of (a) acetone extract and (b) chloroform extract of Uhle box deposit; (c) styrene-butadiene rubber (SBR) copolymer. (Reproduced by permission of the Technical Section, CPPA from X.-Y. Guo, M. Douek, J. Pulp Pap. Sci., 22(11), J431–J439 © 1996.)

Figure 14 DRIFTS spectrum of a solid deposit collected from a pulp dryer screen. (Reproduced by permission of the Technical Section, CPPA from D.F. Leclerc, M.D. Ouchi, J. Pulp Pap. Sci., 22(3), J112–J117 © 1996.)

and 1015 cm\(^{-1}\)) are also present. On the other hand, a Uhle box deposit will contain contaminants from various sources, and is best analyzed following sequential extraction firstly with ethanol, and secondly with chloroform. As shown in Figure 15, FTIR analysis successfully identified the major component of the deposit as a SBR polymer. Polymeric contaminants in market kraft pulp can also be analyzed. Results indicate that polyethylene [9002-88-4], polypropylene [25085-53-4] and latexes are prevalent in the contaminated pulp.
4.3.2 Micro-sized Contaminants

Very small contaminants are more homogeneous, and thus easily analyzed by IR microscopy.\(^{(24)}\) A particularly interesting example is the study of particulate contaminants in recycled paper products. Figure 16 shows the IR spectrum of a polymeric contaminant taken from a paper towel. The spectrum matches that of an ethyl acrylate/styrene copolymer \([25066-97-1]\). Examination of dust particles from an office environment shows that paper products are a major source of dust.\(^{(40)}\)

IR microscopy can also be employed to solve contaminant problems associated with raw stock supplies, pulping operations, sheet formation and the use of recycled pulp. For example, contaminants such as poly(vinyl alcohol) (PVA) \([9002-89-5]\), chitin, defoamers and silicone oils can be identified as well.\(^{(41)}\) The analysis of pulp and paper spots and defects, deposits, fibers, and laminates is very easy with FTIR microscopy. For example, the photomicrograph shown in Figure 17(a) represents a cross-section of a laminate, in this case, a plastic carton.\(^{(16)}\) Four layers are visible in the micrograph. The top and center tie layers are about 100 \(\mu\)m thick and are cellulosic in nature (spectrum: Figure 17c), whereas the two pigmented layers are made of polyethylene (spectrum: Figure 17b).

4.4 Characterization of Papermaking Additives

The ever-increasing use of recycled pulp fibers and the continued trend to lower the grammage of paper sheets have made the judicious use of papermaking additives even more important in maintaining wet- and dry-end sheet strength during the papermaking process. The following examples show that FTIR can play an important role in elucidating the mechanism behind the effect of novel additives on paper strength.

4.4.1 Wet-end Additives

Cross-linking agents such as 1,2,3,4-butane tetracarboxylic acid \([1703-58-8]\) (BTCA) or poly(maleic acid) \([26099-09-2]\) (PMA) improve the wet strength of paper by producing ester cross-linking bonds between cellulose molecules. DRIFTS analysis of BTCA-treated paper\(^{(42)}\) shows that there is a perfect correlation \((r^2 = 0.999)\) between the ester carbonyl band absorbance of the treated paper and its wet-strength retention. As shown in
Figure 18 IR spectra of the sheets treated with 4% PMA and cured at different temperatures for two minutes. The curing temperatures are 120, 130, 140, 150, 160, 170, 180 and 190°C (from bottom to top). (Reproduced by permission from C.Q. Yang, Y. Xu, D. Wang, *Ind. Eng. Chem. Res.*, 35(11), 4037–4042 © 1996 American Chemical Society.)

Figure 18, a five-membered cyclic anhydride is formed as an intermediate because the asymmetric stretching band at 1782 cm\(^{-1}\) is stronger than the symmetric stretching band found at 1850 cm\(^{-1}\), as expected for a cyclic anhydride.

4.4.2 Dry-end Additives and Coatings

Synthetic dry-strength resins such as polyacrylamide [9003-05-8] (PAM) resins have unique properties that make them especially effective as dry-strength additives. Tensile strength generally increases with the amount of additive retained by the sheet and the degree of beating. The extent of PAM retention on handsheets has been studied\(^{(43)}\) with the use of the ATR sampling technique. As shown at the top of Figure 19, the strength of the amide absorption band at 1670 cm\(^{-1}\) seems to increase nonlinearly with beating degree and the retention of PAM, a spurious effect that is in reality due to surface roughness. By using the cellulose band at 1315 cm\(^{-1}\) as an internal standard, the nitrogen content of the sheet as measured by the strength of the amide band now linearly increases with PAM retention, irrespective of beating degree.

Coated sheets contain a variety of additives and fillers like hydroxymethylcellulose [37353-59-6] (HMC), poly(vinyl acetate) [9003-20-7] (PVAc), clay (a mixture of silicates) and calcium carbonate. A DRIFTS spectrum of a coated sheet\(^{(18)}\) is shown in Figure 20. The alkyl ether and carbonyl peaks characteristic of PVAc can be clearly

Figure 19 (a) Relationship between the absorbance of the band at 1670 cm\(^{-1}\) in difference ATR spectra and the amount of PAM retained in the sheets; (b) relationship between the corrected absorbance value at 1670 cm\(^{-1}\) in difference ATR spectra and the amount of PAM retained in the sheets. seen, along with the hydroxyl peak for HMC and those for carbonate and clay.

5 ON-LINE APPLICATIONS: ANALYSIS OF PROCESS LIQUORS

FTIR spectrometers are well suited for on-line applications because of their ability to rapidly determine the concentration of several components at once. The short analysis time being provided by FTIR spectrometry is a prerequisite for process control. Also, because of the need for small path lengths, ATR is the sampling method of choice for aqueous streams, especially in pilot-plant environments and if one carefully selects the right IRE for the application. With the use of multivariate calibration techniques, the chemical components present in liquors (lignin, carbohydrate, and inorganic compounds) can be determined from the FTIR spectra. Individual calibrations can be developed for each type of liquor being monitored. However, because of the limited throughput of chalcogenide fibers, Mid-IR applications cannot use remote sampling locations, and must rely on sampling systems to bring samples to the analyzer, thereby limiting sample throughput. A schematic of a typical on-line installation is given in Figure 21.\(^\text{(44)}\)

On the other hand, in the NIR fiber optics can be used for sensing remote locations. The superior throughput and wavelength accuracy of FTIR spectrometers are essential for using long path lengths, for sampling multiple aqueous streams, and for accurately determining individual components. The use of fiber optics not only increases sample throughput, but is an extremely cost-effective way of interfacing one single instrument to many individual applications which, a few years ago, would have needed their own dedicated instrument. The main drawback is that, since spectra in the NIR region of the spectrum consist of wide overtone and combination bands, a calibration is more difficult to implement, and one must design the calibration experiment carefully to avoid problems such as collinearity. A thorough discussion of the opportunities and challenges presented by process applications of FTIRs is given by Hassell and Bowman.\(^\text{(44)}\)

5.1 Kraft Pulping

A rapid ATR method for determining the effective alkali and inorganic content of kraft process liquors was developed.\(^\text{(45)}\) An ATR spectrum of kraft black liquor is shown in Figure 22. The peak assignments are given in Table 3. Requiring no reagents, the method is faster and more reliable than current laboratory methods. This method has since been commercialized with a mill-hardened spectrometer. Good results are reported when the method is combined with a PLS calibration method;\(^\text{(46)}\) results from the new on-line method closely follow those obtained with a nearby existing on-line titrator. A report has also been issued on the mill performance of this technology.\(^\text{(47)}\) The general assessment is that the method will follow process trends over the long term.

Figure 23 FTIR spectra of white liquor solutions at increasing times (from bottom to top). (Reproduced by permission of the Society for Applied Spectroscopy from J. Bandekar, R. Sethna, M. Kirschner, *Appl. Spectrosc.* 49(11), 1577–1582 © 1995.)

However, an acid wash is required from time to time, and the optical element must be replaced regularly.

The course of the oxidation reaction of white liquor by molecular oxygen has been studied in an ATR sample cell.<sup>(48)</sup> An example of an oxidation run is shown in Figure 23, whereby increasing amounts of sodium sulfate [7775-82-6] (1104 cm<sup>-1</sup>) and sodium thiosulfate 7772-98-7 (995 cm<sup>-1</sup>) are formed as the reaction proceeds.

An univariate ATR method for measuring kappa numbers in laboratory cooks has been proposed.<sup>(49)</sup> The method measures the absorbance produced by dissolved lignin in black liquor at 1118 cm<sup>-1</sup>, and works well for laboratory cooks for which the chip moisture content and the liquor-to-wood ratio is known precisely. However, it would be difficult to implement in the mill where these values are usually not determined with great precision.

Recent advances in FTIR instrumentation and software have made possible the use of the NIR region of the spectrum for determining aqueous components such as dissolved electrolytes. Advantages over previous methods include: no sample preparation, short measurement times, long path lengths and the capacity to use fiber-optic technology for real-time, in situ analysis. A NIR kraft-liquor analysis method has been reported,<sup>(50)</sup> whereby a PLS calibration is carried out for measuring the concentration of sodium hydroxide 1310-73-2, sodium hydrosulfide 16721-80-5 and sodium carbonate 497-19-8. Particularly good results were obtained for effective alkali. A similar method has also been demonstrated for hydrosulfide.<sup>(51)</sup>

5.2 Alkaline Sulfite Anthraquinone Methanol Pulping

Another practical use of liquid-state FTIR spectrometry concerns the analysis of alkaline sulfite anthraquinone methanol (ASAM) liquors, as well as control of the ASAM pulping process. A method for controlling the cooking degree of pulp is described.<sup>(15)</sup> The method
monitors the amount of dissolved lignin present in the liquor during the cook. The method uses correlations of either peak heights or peak integrals between 1400 and 1550 cm\(^{-1}\) with kappa numbers. Correlations with the level of inorganic compounds dissolved in the liquor such as sulfite also gave positive results. An example is shown in Figure 24, which shows the changes in the FTIR spectrum of magnesium-based bisulfite \([7757-88-2]\) (\(\text{HSO}_3^-\)) liquor with cooking time. A decrease in the levels of both free sulfur dioxide \([7446-09-5]\) (\(\text{SO}_2\)) (1331 cm\(^{-1}\)) and bisulfite (1022 and 1064 cm\(^{-1}\)) is accompanied by an increase in the concentrations of lignin (1512 cm\(^{-1}\)) and lignosulfonates \([8061-54-9]\) (1037 cm\(^{-1}\)).

5.3 Other Applications

The degree of nitration of cellulose nitrate \([9004-70-0]\) was determined\(^{23}\) with the combination of a gel permeation chromatography (GPC) column and an on-line transmission flow cell. The solvent was tetrahydrofuran \([109-99-9]\) (THF). The antisymmetric nitrate stretching region around 1650 cm\(^{-1}\) was used for estimating the degree of nitration.

Table 4 summarizes the scope of pulp and paper applications of FTIR spectrometry with regard to analyte, choice of sampling method, matrices, and key references.

### 6 QUALITY CONTROL AND TROUBLESHOOTING

In this section, we will briefly discuss problems that affect data quality such as deviations from Beer’s law, apodization, low resolution, and spectral noise caused by excessive vibration. Griffiths and de Haseth\(^1\) have discussed these problems and their effects on quantitative analysis in more detail.

#### 6.1 Instrument Performance Issues

##### 6.1.1 Laboratory Performance

In most cases, the FTIR spectrometer will be located in the technical department, which is very often located next to the mill. Low- and high-frequency mechanical vibrations are the norm, and care must be taken to insulate the instrument from vibrations. If not, a stronger apodization must be used so that lowering the resolution preserves the integrity of the data. Most pulp and paper applications deal with bands that are relatively broad, and so the choice of the apodization function

will not affect band shapes significantly. However, some spectra will exhibit a combination of sharp peaks, i.e. lignin, and broad peaks such as carbonate, sulfate, etc., and so the choice of apodization will depend on the application. In general, a stronger apodization will distort sharp peaks very significantly. Also, sharp peaks with an absorbance greater than unity will exhibit deviations from Beer’s law even if the extent of apodization is small. Therefore, it is best to tailor the application so that none of the peaks will have an absorbance greater than 0.7. For instance, in an ATR application, one would select an optical element with a shorter effective path length.

6.1.2 Performance at Mill Sites

Instrument air which is available at mill sites is usually used for operating pneumatic valves, not for purging optical instrumentation, and its moisture content often fluctuates, especially in the summer. Since this could impair long-term performance of the optical system, it is best to use an instrument that either has a permanently purged optical compartment, or one that is continually dried by a desiccant which is replaced on a regular basis.

6.2 Data Quality Issues

6.2.1 Reststrahlen (Inversion) Bands

Samples with microscopic crystalline domains such as minerals often display spectral artifacts called reststrahlen or inversion bands, which are produced by specular reflection when analyzed by DRIFTS even at very low concentrations, whereas amorphous samples like lignin do not. Similar anomalous dispersion effects with pulp fibers have been reported. An example of these effects is shown in Figure 25: spectral distortions can still be seen at a concentration as low as one percent. On the other hand, no specular reflection is observed with extracted lignin samples. This effect has been attributed to the structural features present in the cellulose portion of pulp fibers. Therefore, DRIFTS analysis of pulp fibers must be done at the maximum dilution ratio dictated by the application, but not so much that any useful spectral features are lost.

6.2.2 Optimization of Attenuated Total Reflectance Sensitivity

Some ATR applications call for enhanced sensitivities. One can either increase the penetration depth, or the number of reflections. Of the two, the latter is the most effective since increasing the penetration depth only further distorts the fingerprint part of the spectrum. This can be done quite easily by selecting an optical element with a conical angle of 30° instead of 45°, or by buying a flow cell that accommodates a longer optical element. A conical angle of 30° effectively doubles the path length, which should satisfy most requirements.

7 DEVELOPMENT OF QUANTITATIVE METHODS

In this section, we will show a few typical examples of quantitative method development. We will also talk about the need for sound experimental planning during the design and calibration phases of a typical multivariate calibration method.

7.1 Univariate Calibration

When performing an univariate calibration, it is necessary to locate an isolated band so that the analyte can be quantified without interferences. Lignin exhibits some sharp absorption bands that do not significantly overlap with others. In particular, the band at 1510 cm⁻¹ is amenable to peak-area measurements, especially for dry pulp. However, the water band at 1640 cm⁻¹ is very wide and, even when present in small quantities, interferes significantly with any measurement which depends on a subjective choice of baseline. Nevertheless, a DRIFTS method, which estimates the amount of lignin in air-dried unbleached pulps, has been developed. Lignin-free cotton linters were used as the reference material. A lignin spectrum is thus obtained after spectral subtraction of the cellulose contribution. As shown in Figure 26, a linear relationship is found between the area of the band at 1510 cm⁻¹ and kappa number for a wide variety of species. However, the data show a significant amount of scatter, especially for low kappa numbers, probably
because of differences in the amount of specular reflection emitted by each pulp sample. In fact, it is reported that the results are no better than those obtained with traditional analysis. Therefore, univariate calibration must be used only when one is reasonably sure that a single physical phenomenon such as Beer’s law or internal reflection is responsible for the spectral changes being monitored. Since most pulp and paper applications of FTIR deal with complex matrices, multivariate calibration must be used so that optimal results are obtained.

7.2 Multivariate Calibration

The selection of independent calibration samples will be discussed in the context of modern experimental design principles, and with regard to the analysis at hand. We will then present an example of a typical experimental design, followed by a brief discussion of the respective merits of the CLS and PLS calibrations, in a pulp and paper context.

The selection of calibration samples is essential to the success of any method, particularly when dealing with a large number of components per sample. Two-level factorial designs enable the experimenter to detect any number of interactions between components, and permit the construction of robust models. Component concentrations are varied in a systematic and orthogonal fashion, so that the greatest amount of information is gathered from a small number of samples. These types of design allow the detection of interaction and nonlinear effects. When one is reasonably sure that no significant interactions occur, a half-factorial design is usually sufficient and more effective, since only half the number of samples is needed. Table 5 shows such a half-factorial calibration design for a four-component hypothetical green liquor for which the concentration range (in g L\(^{-1}\) as Na\(_2\)O) is as follows: EA = 5(–) to 45(+); NaHS = 5(–) to 35(+); Na\(_2\)CO\(_3\) = 30(–) to 80(+); Na\(_2\)SO\(_4\) = 2(–) to 12(+). The target concentration usually constitutes the center point of the range. The extremes of the range are calculated so that they lie outside the possible range of value found in the mill. Another type of design is the constrained mixture design, which is most suitable for modeling the spectral behavior of mixed-species pulps such as spruce, pine and fir. Depending on the application, both types of design can be employed for selecting the composition of samples.

### 7.2.1 Classical Least Squares Calibrations

Pulp and paper samples have complex matrices and usually contain minor constituents that are not of interest to the researcher. More often than not, these minor constituents exhibit a significant spectral response. Also, the spectra of these samples exhibit spurious effects such as baseline shifts that are hard to characterize, let alone quantify. Unfortunately, a CLS calibration requires that
the concentration of every constituent be known and assumes that the response is due entirely to constituents present in the calibration. Therefore, CLS calibrations have very little utility for pulp and paper users of FTIRS, and will not be discussed further.

7.2.2 Partial Least Squares Calibrations

The PLS calibration technique is tailor-made for pulp and paper applications, since only knowledge of the constituent of interest is required for the calibration. In addition PLS can sometimes be used for predicting unknown samples, even in the presence of contaminants not originally present in the original calibration samples. The PLS naturally lends itself to the accurate determination of pulp constituents. For example, the proportion of phenolic hydroxyl in milled wood lignins (MWL) was predicted versus that determined by aminolysis. Results are shown in Figure 27. Best results are achieved when the spectral range from 800 to 2000 cm⁻¹ is used. The PLS calibration gave absolute standard errors of 0.06% and prediction errors of 0.11%, a result which is six times better than that obtained by a simple linear regression based on the absorbance of the acetoxy bands at 1744 and 1766 cm⁻¹. Another method uses the DRIFTS technique to rapidly determine lignin and carbohydrates such as arabinose [5328-37-0], galactose [59-23-4], glucose [50-99-7], mannose [3458-28-4] and xylose [25990-60-7] in pulp, as well as assess process properties such as yield. Table 6 provides a checklist for choosing the best calibration method.

8 COMPARISON WITH OTHER SPECTROSCOPIC METHODS

In this section, we will first compare FTIRS with other spectroscopic methods such as NIR dispersive spectrometry, Raman spectroscopy and MS, and then briefly examine business issues relating to the purchase and maintenance of process instrumentation.

8.1 Comparison of Technology

8.1.1 Near-infrared Dispersive Spectroscopy

In the NIR region (4000 to 14 000 cm⁻¹) the weakness of overtone bands results in higher detection limits, which can be overcome by using thicker or undiluted samples. This enables the sample to be analyzed with little or no preparation. Much longer path lengths (from 0.5 mm to 1 cm) are also available for aqueous samples. NIR absorption bands are sensitive to their local environment, and one can distinguish between polar, steric and hydrogen bonding effects. In the reflectance mode, the penetration depth of IR radiation is about 10 to 100 µm, versus a few millimeters for NIR radiation. Detection limits are 100 parts per million for NIR whereas for the Mid-IR these are about 1 part per million for the transmission mode.

A comparison between the use of NIR and FTIR for the analysis of pine lignin in pulped wood fibers was performed with the use of the transmission method. Even though the two methods yielded similar calibration results, sample preparation and analysis for the NIR technique were much faster and simpler. On the other hand, FTIR gave the best standard error of prediction. Therefore, the advantages of using a FTIR spectrometer

are not so obvious, especially for qualitative analysis, since cheaper dispersive instruments have sufficient throughput for most laboratory applications.

The latest trend in NIR spectroscopy is to use an acoustic-optic tunable filter (AOTF) as a monochromator. This technology has been reviewed elsewhere. An AOTF device has a number of advantages. First, a NIR AOTF spectrometer is cheaper than a FTIR spectrometer. Second, it can scan very rapidly and more than one wavelength can be recorded simultaneously. Third, it has a large aperture. However, resolution is not constant with frequency and is modest at best (between 30 and 50 cm\(^{-1}\) at 10,000 cm\(^{-1}\) in the noncollinear configuration) and the throughput, although greater than that of a dispersive instrument, is not sufficient for multiple-point fiber-optic applications. Finally, AOTF instruments do not have the frequency accuracy provided by the laser referencing of FTIR spectrometers, and need to be re-calibrated after servicing, thereby generating significant calibration maintenance costs.

The advantages of using a FTIR spectrometer for demanding NIR applications are thus readily apparent, especially when one desires to use a single instrument for developing quantitative methods to be applied at multiple sampling locations throughout the mill site without the need for re-calibration.

### 8.1.2 Classical Raman and Fourier Transform Raman Spectroscopy

Since both IR spectroscopy and Raman spectroscopy deal with molecular vibrations, the two techniques can be compared. The kind of information one can gather from a Raman experiment is similar but not identical to that obtained with IR spectroscopy. A molecular vibration is Raman-active if a change in polarizability occurs during the transition, whereas it is IR-active if a change in dipole moment is produced by the vibration. Thus, strongly covalent bonds have intense Raman bands, whereas molecules with strongly polar bonds produce intense IR bands. For example, water is a strong IR absorber, but a weak Raman scatterer. Water can therefore be present in samples analyzed by Raman spectroscopy. Since the selection rules are different for the two types of spectral transition, the information which one can gather from a Raman spectrum complements that which is obtained from an IR spectrum. Raman technology has been reviewed by Christiansen et al. Pulp and paper applications of Raman spectroscopy are discussed in a review.

Raman scattering is a very inefficient process, and so the intensity of bands is very small, unless the Raman process can be enhanced by resonance. Traditionally, most pulp and paper samples could not be analyzed with classical Raman spectroscopy because of the presence of laser-induced fluorescence (LIF) produced by lignin and its degradation products. LIF completely swamps the Raman signal, unless it is minimized when using NIR excitation, in combination with a FTIR interferometer. However, a small residual fluorescence background still remains for samples that are high in lignin content. Nevertheless, the advent of Fourier transform Raman spectroscopy (FTRS) has enabled a number of previously inaccessible applications such as elucidating the mechanism of color reversion to be carried out. FTRS also benefits from the throughput, multiplex and laser-reference advantages. Thanks to the last advantage, the sharp spectral features found in a Raman spectrum are better preserved than with a dispersive instrument since there is no peak broadening during signal averaging. However, since the Raman signal varies as the inverse fourth power of the wavelength, peaks generated in FTRS with NIR excitation are weak and, for samples with high lignin content such as wood, difficult to quantify against the background produced by residual fluorescence. Also, data acquisition is still slow because of the poor noise performance of NIR detectors, as compared to the performance of visible-range detectors used for classical Raman spectroscopy. High-powered lasers are used for circumventing this problem, but these generate a thermal background that is just as high as a fluorescence background. Finally, the cost of FTRS is double that of FTIR instruments, not to mention that excitation lasers need to be replaced every two or three years.

In general, for low-fluorescence samples such as chemimechanical pulp, semi-bleached pulp and paper surfaces, Raman spectroscopy is more advantageous than IR spectroscopy since the amount of moisture in the sample does not interfere with the measurement. On the other hand, FTIRS is the preferred method for the analysis of wood and pulp samples having high levels of lignin and fluorescent chromophores.

### 8.1.3 Mass Spectrometry

Secondary ion mass spectrometry (SIMS) is the most widely used mass-spectrometry sampling technique for pulp and paper applications. SIMS is a solid-surface analysis technique that destructively samples the topmost layer of the surface by focusing an energetic beam of ions onto a solid-phase sample and secondary ions are sputtered from the surface and analyzed by a mass spectrometer. Even though the penetration depth of these ions is much smaller than 1 \(\mu\)m, the IR-spectrometry counterpart for this technique is the ATR sampling technique. SIMS mainly provides information about the spatial distribution and nature of trace fragments from heavier inorganic species such as the calcium in calcium carbonate and simple organic molecules, whereas ATR provides nondestructive bulk analysis of the uppermost 1 \(\mu\)m of the surface. Ideally, one should...
perform a preliminary ATR characterization followed by the more sensitive SIMS. An example is that of dry-strength additive analysis.\(^{(65)}\) Whereas ATR can detect strongly absorbing functional groups such as the amide absorption band in PAM, it cannot distinguish between additives having the same amide functional group but different types of aliphatic chains. On the other hand, these aliphatic groups can be readily identified and differentiated by the SIMS technique, thanks to differences in their fragmentation patterns. The technique is particularly useful for measuring the effectiveness of sizing agents. Detter-Hoskin and Busch\(^{(65)}\) have discussed pulp and paper applications of the SIMS technique.

Table 7 summarizes some of the advantages and disadvantages of different spectrometric methods being used in pulp and paper applications.

### 8.2 Business Issues Relating to Process Control Instrumentation

Improvements in IR analyzer technology, combined with advances in digital control and process-control systems, have led to increased use of FTIR spectrometers in closed-loop automated control applications. In the following paragraphs, we will briefly examine some of the most important issues involved in the use of IR analyzers for process control applications.

Key requirements for using an IR analyzer for closed-loop control are repeatability, accuracy, reliability and suitable response time. Because of the need for recording a reference spectrum from time to time, most present-day installations use the slip-stream configuration and a sample conditioning system shown in Figure 21. This enables a single analyzer to sample different types of process streams. However, this introduces a significant dead time, during which the analyzer is not available. This dead time should be no more than one-sixth of the time constant of the process. For pulp and paper operations such as the digester and recausticizing units, this time constant is often measured in hours. Therefore, an effective measurement time of five to ten minutes is sufficient. Nevertheless, the increased availability of multiple in situ fiber-optic probes monitored with a single instrument is making the use of IR analyzers much more attractive for process-control applications, since the dead time is effectively reduced to zero. San Giovanni\(^{(66)}\) has reviewed in detail the technical requirements for process-control instrumentation as well as the economic aspects of those requirements.

#### 8.2.1 Purchasing Considerations and Maintenance Requirements

No instrument, whether used for laboratory analysis or for process-control measurements, is free of maintenance requirements. The cost of purchasing a laboratory instrument such as an IR spectrometer is generally measured against the need for increased analytical capability. Such capability will not be generally used every day, but will be available when needed. Purchasing costs are therefore amortized over the projected life of the instrument, whereas maintenance costs are absorbed into operating budgets. Since there is no direct link to benefits, no consideration is given to the amount of time needed to achieve complete return on investment (ROI).

The situation is radically different for a process-control IR analyzer. Compared to other types of instrumentation for process control, an analyzer is relatively expensive, more complex and sensitive to its environment, and requires more regular maintenance by trained personnel. Therefore, capital expenditures leading to an installation must be justified by the benefits generated through continuous use. An example of a cost-benefit analysis is given below.

#### 8.2.2 Benefits and Costs: An Example

The investment cost that is necessary for the purchase of an on-line IR analyzer is discretionary in nature, i.e., directly related to improved profitability. Benefits in pulp and paper mills are usually linked with increased production and/or reduced process and product-quality variability. For example, assuming that a typical mill produces 1000 tons of pulp per day, implementation of a closed-loop digester control system will generate annual savings of between US$500 000 to US$1 000 000, mainly through reduced use of chemicals, more consistent liquor quality, increased production, and lower downgrading costs. If the cost of the analyzer is US$250 000, the ROI is therefore between three to six months. Typical assumptions on improvements to be realized are:

1. reduced white liquor flow (5 to 10%);
2. lowered K number standard deviation (30%), reduced bleach-plant chemical consumption ($1 per K number deviation per ton);

3. drop in off-grade production (25%), penalty for off-grade pulp (US$30 per ton);
4. increased production (1%), marginal profit on additional tonnage (US$100 per ton).

Therefore, even though savings are mill-specific and, quite often proprietary, it is nevertheless possible to give a range of probable savings by making general assumptions on the process improvements made after implementation of a closed-loop control application. Van Fleet (67) has given a very detailed discussion of benefits and costs associated with closed-loop control applications.

Mechanical pulps are those where the starting wood is rendered into a suspension of fibers by the application of mechanical energy. Most of the lignin component is retained in the fibers by this process. The yellowish coloration of wood fiber is a consequence of the presence of chromophores in the lignin that absorb both visible and ultraviolet (UV) light. In most cases, the fibers must be bleached before they are acceptable for their final use. Lignin-containing fibers are also susceptible to yellowing when exposed to UV light. To study the chemistry of these processes in pulp fibers, a technique capable of detecting chromophores in materials that both absorb and scatter radiation is needed. Diffuse reflectance ultraviolet/visible (UV/VIS) spectroscopy is such a technique. For nonscattering materials, the Beer–Lambert law provides a simple linear relationship between absorbance and the concentration of absorbers. This has been used for the analysis of soluble lignins and pulping liquors. For scattering materials, there is no similar simple linear relationship between reflectance and concentration of absorbers. A single reflectance measurement from an opaque sample can be related to the ratio of absorption to scattering by the Kubelka–Munk remission function, $F(R_\infty) = k/s = (1 - R_\infty)^2/2R_\infty$, where $R_\infty$ is the reflectance of an opaque sample, $k$ is the specific absorption coefficient and $s$ is the specific scattering coefficient. The specific absorption coefficient $k$ is linearly related to absorber concentration. If the scattering coefficient remains constant, the remission function is proportional to chromophore concentration. However, for many samples of interest, such as pulps prepared by different mechanical processes, scattering is not constant. Here, it would be uncertain whether a difference in remission function should be attributed to a change in absorption or a change in scattering. Also, in samples where the chromophores are not homogeneously distributed throughout the sample thickness, such as sheets yellowed by light, the linearity of the remission function no longer holds. In such cases, $k$ can be calculated explicitly by taking additional reflectance measurements from thin transmitting samples that are suspended over backgrounds of known reflectance. While spectra of $k$ versus $\lambda$ (wavelength) are usually broad and featureless, difference spectra can reveal a surprising amount of detail about the changes in chromophore content.

1 INTRODUCTION

Higher plants contain three types of biological polymers: celluloses, hemicelluloses, and lignins. Celluloses are linear polymers of the glucose dimer cellobiose, while hemicelluloses are complex polysaccharides containing a variety of carbohydrate building blocks. Lignins are polymers of methoxy-substituted phenylpropane. Papermaking fiber is obtained from plants by disintegrating the woody tissue into an aqueous suspension of its constituent fibers. The fibers are bleached to an appropriate whiteness and are then “reassembled” at the paper machine into sheets. The majority of paper produced in the world today originates from wood fiber, with small contributions from nonwood sources such as bamboo, kenaf, sugar-cane bagasse and straw.

There are two major ways to disintegrate plant tissue into fibers. In chemical pulping, lignin is removed by hydrolysis. The dominant process used today is kraft
pulping, alkaline hydrolysis catalyzed by sodium sulfide. This process and the subsequent bleaching stages remove not only lignin, but also the hemicellulose component of the fibers. Kraft pulping produces fibers that form a strong sheet and that can be bleached to a high and stable whiteness, at about 45% yield based on the starting wood.

In mechanical pulping (also known as high-yield or ultra high-yield pulping), mechanical energy is applied to disintegrate wood into fibers. The mechanical energy is applied either by grinding or by refining; feeding wood chips into the center of two grooved rotating discs and collecting fibers at the periphery. Mild chemical pretreatments, such as steaming at up to 130°C, or short digestion with bisulfite or sulfate, may be used to alter the material properties of the wood and assist disintegration into intact fibers. These treatments are not severe enough to dissolve much of the lignin, and the yield of fiber from wood is at least 80%, more commonly 90–95%. Almost all new mechanical pulp installations built since 1975 use refiner pulping techniques.

Mechanical pulps have traditionally been restricted to the manufacture of short-life, low-whiteness products such as newsprint. However, projected fiber shortages and the high capital cost of new kraft mills have made the use of bleached mechanical pulps in higher value paper grades increasingly attractive. Softwood thermomechanical pulp (TMP) can be bleached economically to ISO (International Standardization Organization) brightness of about 80% with alkaline hydrogen peroxide, while 87% is achievable for chemithermomechanical pulp (CTMP) from hardwoods. While acceptable for many uses, this is still less than the 92% ISO brightness possible for fully bleached kraft pulp. The most serious barrier to wider use of mechanical pulps is their tendency to yellow rapidly under UV irradiation. Both of these limitations arise from the presence in the lignin of small concentrations of chromophores, groups that absorb strongly near-UV (300–400 nm) or visible (400–700 nm) light.

Changes in chromophore content that result in perceptible, even severe, changes in color usually involve only a small number of lignin groups. Often, they cannot easily be detected by techniques such as NMR (nuclear magnetic resonance), or even vibrational spectroscopies, especially in the solid state. Thus, diffuse reflectance UV/VIS spectroscopy is often the best method for studying chromophore changes in wood fibers.

2 ORIGIN OF ULTRAVIOLET/VISIBLE ABSORPTION IN MECHANICAL PULPS

Mechanical pulps absorb strongly in the UV region, from 200 nm to greater than 360 nm. These absorptions tail into the visible region and contribute to the characteristic colors of various woods. Chromophores with maxima in the visible region (e.g. quinones, flavones) also exist. Cellulose and hemicellulose contain largely saturated bonds to carbon and therefore contribute very little to this absorption. Lignin, due to its benzenoid structure, is responsible for most of the UV/VIS absorption of mechanical pulps, although there is some contribution from low-molecular mass extractives. This is true even for highly colored woods such as western hemlock, red cedar, etc.

2.1 The Nature of Lignin

The biosynthesis of lignin occurs by radical polymerization of one or more of the propenyl phenol precursors shown in Figure 1. Lignin units are classified according to their degree of methoxyl substitution. Those without methoxyl substitution are p-coumaryl units, those with one o-methoxyl group are guaiacyl units, and those with two o-methoxyl groups are syringyl units. Coniferous woods contain almost exclusively guaiacyl units and 1–5% p-coumaryl units, while deciduous species contain approximately 60% syringyl units and 40% guaiacyl units. Grasses can contain all three types of lignin unit.

The biosynthesis of lignin is a radical reaction, most often described as a random process leading to a statistical distribution of the possible bonding patterns. However, Davin et al. recently isolated a so-called dirigent protein that couples lignin precursors stereospecifically. This is the first clear evidence that lignin biosynthesis may be more precisely controlled than previously thought.

Unlike most biological and synthetic polymers, lignins contain a variety of interunit bonding patterns. Lignin structure is usually specified by the frequency of the various bonding patterns and functional groups, expressed as a percentage of the total number of phenyl propane, or C₉, units. Some of the more important structures are shown in Figure 2. Side-chain carbons are labeled, moving away from the benzene ring, as α, β and γ. Benzene carbons are numbered, with the carbon bearing the side chain as carbon 1.

![Figure 1](image-url) Bioynthesis of lignin occurs by radical polymerization of propenyl phenol precursors. R₁ = R₂ = H are p-coumaryl units, R₁ = H and R₂ = OMe are guaiacyl units, and R₁ = R₂ = OMe are syringyl units.
Approximately 10–15% of lignin units have a free (unetherified) phenolic group, which is one of the most reactive functional groups. The most frequent interunit linkage is the $\beta$-O-4 structure, where the phenolic oxygen of one unit is bonded to the $\beta$ carbon of the next. In guaiacyl lignins, the unmethoxylated ortho position can bond at a $\beta$ carbon, giving the fused ring phenylcoumaran structure. Guaiacyl units can also form C–C bonds at the unmethoxylated ortho position, yielding biphenyls. Karhunen et al.\cite{4-6} have proposed that biphenyl units are bonded in guaiacyl lignins as dibenzodioxicin structures. Substituted cinnamaldehyde and cinnamyl alcohol structures are end units of the polymer. Cinnamaldehydes have an intense UV absorption at 350–360 nm that contributes to the color of wood. Finally, $\alpha$-quinones, although present in very small amounts (about 0.7%), are also considered as one of the major contributors to the color of wood and mechanical pulps.

### 2.2 Absorption of Substituted Benzenes Related to Lignin

The maxima, extinction coefficients and designations of the three absorption bands for benzene in solution are shown in Table 1.\cite{7} The band designations $1B$, $1La$, and $1Lb$ arise from the Platt system of nomenclature for polycyclic aromatic hydrocarbons,\cite{7} of which benzene is the simplest example. The two longest wavelength bands (256 nm, 203 nm) are symmetry forbidden, but have a finite intensity because they are vibronically coupled to the fully allowed transition at 180 nm.

$^a$ Values from Jaffé and Orchin\cite{7}. Substitution on the benzene ring shifts the absorption maxima of the $1La$ and $1Lb$ transitions by roughly equal amounts and increases their intensity, largely as a consequence of resonance effects. The wavelength shifts are always to the red, regardless of whether the substituent is electron donating (ortho, para directing) or electron withdrawing (meta directing). The $1B$ band is also red shifted, often to wavelengths longer than 200 nm.

In disubstituted compounds two types of shifts are observed.\cite{8} If both substituents are of the same type ($o$, $p$-directing or $m$-directing), there is no additive effect due to the second substituent; the band displacements are those observed for the most displaced monosubstituted compound. Thus the $1La$ band (203 nm in benzene) is shifted by 26.5 nm in benzoic acid, 65 nm in nitrobenzene, and 61 nm in $p$-nitrobenzoic acid.\cite{7}

If one of the substituents is electron donating and the other is electron withdrawing, further wavelength shifts are observed when the second substituent is added,\cite{7-10} as shown in Table 2. For example, in the

hydroxybenzaldehydes, the $^1L_a$ band is shifted by 53 nm in the $o$-isomer and 51 nm in the $m$-isomer, almost the sum of the shifts for phenol (7 nm) and benzaldehyde (46 nm). The wavelength shift in $p$-hydroxybenzaldehyde is greater than additive, 80 nm, and is large enough to obscure the $^1L_b$ band. In the $o$- and $m$-disubstituted compounds, it is the $^1L_b$ band that is red shifted by an amount greater than the sum of the individual substituent shifts.

The spectra of trisubstituted benzenes with one electron-withdrawing and two electron-donating substituents contain the most red-shifted bands found in the constituent disubstituted compounds.$^{(11)}$ This is illustrated in Table 3 for 3,4-dimethoxybenzaldehyde. The $^1L_a$ band is the most red-shifted in $p$-methoxybenzaldehyde (267 nm), while the $^1L_b$ band is the most red shifted in $m$-methoxybenzaldehyde (306 nm). Both of these red-shifted bands appear in 3,4-dimethoxybenzaldehyde.

2.3 Absorption and Determination of Soluble Lignins

Soluble lignins are obtained as byproducts of chemical pulping. They can also be obtained from wood or lignin-containing pulp by acidolysis or enzymic treatment, or by milling followed by solvent extraction (so-called milled-wood lignin). The use of UV/VIS absorbance spectroscopy to quantify such lignins, and as an aid to study their chemistry, will be described briefly in this section.

Figure 3 shows the spectra of two milled-wood lignin samples, one obtained from TMP made from a mixture of eastern North American black spruce and balsam fir, and the other obtained from aspen wood. These spectra are typical of most soluble lignins. Above 300 nm, the absorbance declines continuously, without any clear features. A discrete characteristic maximum occurs at about 280 nm, and a shallow minimum appears at around 260 nm. Below 260 nm, the absorbance increases sharply with decreasing wavelength and the spectrum depends somewhat on the solvent and the specific lignin preparation. In some cases, another maximum is observed at around 230 nm as in Figure 3. In others, this second absorption maximum is blue shifted to about 205 nm.

The absorbance at 280 nm (less often at 205 nm) is the basis of several techniques for the quantitative

Figure 3  Absorbance spectrum of milled-wood lignin obtained from spruce/balsam fir TMP (0.025 g L$^{-1}$) and aspen wood (0.05 g L$^{-1}$) dissolved in 80 : 20 2-methoxyethanol–water.
determination of lignin, according to the Beer–Lambert law, Equation (1).

\[ A = D IC \]  

(1)

\( A \) is the absorbance, \( l \) the path length in cm, \( D \) the absorptivity, and \( C \) the concentration. The absorptivity \( D \) is analogous to the more familiar extinction coefficient \( e \). Concentration of lignin solutions is usually expressed in g L^{-1}, so that the units of \( D \) are L g^{-1} cm^{-1}. The absorptivity depends on species and solvent, and varies from 10 to about 26. Summaries of absorptivities are available in reviews by Lin,\(^{12}\) and Fengel and Wegener.\(^{13}\)

2.3.1 Determination of Soluble Lignins

Although lignin model compounds are soluble in a wide range of solvents, the choice of solvent for isolated lignins is more limited. Nonetheless, solvent selection is important for quantitative work and care should be taken to assure complete dissolution of the material.

Lignosulfonates are usually soluble in water or water–ethanol mixtures. Lignin from alkaline pulping processes is soluble in water at alkaline pH, but precipitates at neutral or lower pH. A widely used solvent for this lignin and milled-wood lignin is a 2 : 8 mixture of water with either 2-methoxyethanol or 1,4-dioxane. Dimethylformamide or hexafluoropropanol have also been used for intractable samples.

The following procedure for determination of a soluble lignin sample is adapted from Lin:\(^{12}\)

1. Weigh 0.5 g of lignin into a 1 L volumetric flask and make up to the mark with solvent. For aqueous solutions, the pH is adjusted to 5 with acetic acid prior to full dilution.
2. Avoid heating or exposure to UV light. If possible, remove oxygen by bubbling a gentle stream of nitrogen (e.g. from a syringe tip) through the solution for 5–10 min. This is particularly important for solutions prepared at alkaline pH, since the phenolate ion reacts readily with oxygen.
3. Dilute the stock solution 10-fold to make the final solution. Determine the absorbance using pure solvent in a matching cuvette as the reference. For quantitative work, the absorbance at 280 nm is usually used. If necessary, the dilution should be adjusted so the absorbance is between 0.2 and 0.8, the most highly linear range for the Beer–Lambert law. A spectrum can be acquired, if desired.
4. Determine the concentration of lignin from the absorbance using the Beer–Lambert law and an appropriate value of the absorptivity. The preferred procedure, of course, would be to construct a calibration graph of absorbance versus concentration, using a known pure sample of the lignin under study.

2.3.2 Determination of Lignin in Wood or Pulp

In addition to determining soluble lignins, UV absorbance has also been used to determine the lignin content of solid plant tissue or pulp. The solid sample is solubilized by an appropriate chemical treatment, usually acid hydrolysis, and the lignin content is determined from the absorbance at 280 nm. Dence\(^{14}\) has summarized various techniques reported in the literature. The acetyl bromide method has gained general acceptance because of its simplicity, precision and lack of interference from nonlignin materials. A procedure according to Dence\(^{14}\) is described here:

1. Wood samples are ground in a Wiley mill and the 40–60 mesh fraction is Soxhlet-extracted with 1 : 2 ethanol–benzene. Pulp samples do not require milling, but are solvent exchanged through acetone and dried at 60°C and 20 mmHg before the ethanol–benzene extraction.
2. Sample size is generally 5 mg for woods and 10–15 mg for pulp. The samples are placed in 15 mL glass vessels containing 10 mL 2 M NaOH and 25 mL acetic acid.
3. The samples are heated in an oven at 70°C, with swirling at 10-min intervals.
4. The digested samples are transferred to 100-mL flasks containing 10 mL 2 M NaOH and 25 mL acetic acid. After rinsing the bottles, the solution is made up to the mark with acetic acid.
5. The absorbance is measured at 280 nm and the lignin content is determined using Equation (2)

\[ \text{Lignin} \% = \frac{100(A_s - A_b)V}{DW} - B \]  

(2)

\( A_s \) is absorbance of the sample, \( A_b \) is the absorbance of a blank sample carried through the digestion procedure, \( V \) is the solution volume in liters, \( D \) is the absorptivity of a lignin standard, and \( W \) is the mass of the sample in grams. \( B \) is a correction factor for pulp samples; \( B = 1.70 \) for kraft pulps and 1.38 for sulfite pulps. As in the determination of soluble lignins, it is important to use the appropriate value of the absorptivity. Dence has compiled representative values from the literature.\(^{14}\) The best procedure, when possible, is to construct a calibration graph for the lignin in question where the lignin content has been determined by some standard procedure such as Klasson lignin analysis.
2.3.3 Absorption Difference Spectra: $\Delta \varepsilon$ Methods

Difference spectroscopy has been enormously useful in interpreting the UV/VIS spectra of lignins. In this technique, the absorption spectrum measured before a given chemical treatment is subtracted from that recorded after the treatment (or vice versa). In the simplest case, a compound, $C$ (concentration of $C$), is transformed to a product $P$ (concentration of $P$). At any time during the reaction, these quantities are related by mass balance, Equation (3), where $C_0$ is the initial concentration of $C$.

$$P(t) + C(t) = C_0$$  \hspace{1cm} (3)

The difference in absorbance $\Delta A$ is given by Equation (4),

$$\Delta A = l(\varepsilon_P P(t) + \varepsilon_C C(t) - \varepsilon_C C_0)$$  \hspace{1cm} (4)

where $l$ is the path length through the sample cell, and $\varepsilon_P$ and $\varepsilon_C$ are the extinction coefficients for $P$ and $C$, respectively. Substituting the mass balance for $C_0$ yields Equation (5).

$$\Delta A = l(\varepsilon_P - \varepsilon_C) P(t) = l\Delta \varepsilon P(t)$$  \hspace{1cm} (5)

Note that absorptions by groups that are unaffected by the chemical treatment will cancel in the subtraction.

Lin(12) has described procedures for the measurement of ionization difference spectra. Absorption difference spectra have been used to estimate the content of phenolic groups, carbonyl groups,(15,16) ethylenic double bonds,(16) noncondensed phenolic groups(17) and phenylcoumarans(18,19) in soluble lignins, and to study the photochemistry of lignin solutions(20,21). Two brief examples are given below to illustrate the technique.

The absorption of a phenolate ion is shifted by at least 10 nm to longer wavelength relative to the corresponding phenol. If electron-withdrawing groups are conjugated with the benzene ring, especially when para to the phenol function, the shifts are considerably larger.

example, 3,4-dimethoxyacetophenone and 3-methoxy-4-hydroxyacetophenone both have an absorption peak at 310 nm in neutral solution. In alkaline solution, this peak is unchanged in dimethoxyacetophenone, but is shifted to 350 nm for 3-methoxy-4-hydroxyacetophenone.

Adler and Marton\(^{15}\) estimated the numbers of phenolic and etherified lignin units containing carbonyl groups in either the $\alpha$ or $\gamma$ positions of spruce milled-wood lignin, by determining such ionization difference spectra before and after reduction with NaBH$_4$. The positions of the absorption maxima for the various lignin structures and their estimated content in spruce milled-wood lignin are shown in Table 4. The appropriate values of $\Delta\varepsilon$ to use in Equation (5) were determined from experiments on appropriate model compounds. Note that, even though the difference spectra for etherified $\gamma$-carbonyls and phenolic $\alpha$-carbonyls both have maxima in the alkaline-borohydride difference spectrum at 340–350 nm, they could be easily distinguished because the phenolic carbonyls are reduced much more slowly.

In another study, Marton and Adler\(^{16}\) estimated the content of $\alpha$–$\beta$ double bonds in spruce milled-wood lignin by comparing the ionization difference spectra before and after catalytic hydrogenation. The results are summarized in Table 4. This experiment also yielded estimates of the amounts of etherified conjugated $\alpha$ and $\gamma$ carbonyl groups that agree well with those obtained by the borohydride reduction experiment.

3 ULTRAVIOLET/VISIBLE DIFFUSE REFLECTANCE SPECTROSCOPY

Figure 4 shows the diffuse reflectance spectra of unbleached and peroxide-bleached TMP from black spruce. Reflectance is the ratio of the intensity of reflected to incident light, and is thus mathematically analogous to the transmittance of the Beer–Lambert law. Unlike transmittance, however, reflectance is not easily rendered to a quantity proportional to chromophore concentration.

Kubelka and Munk developed the basic theory of diffuse reflectance in the 1930s,\(^{22}\) and Van den Akker\(^{23}\) extended it to paper shortly afterwards. However, the arduous calculations required to generate spectra severely limited its use. The development of microprocessor-controlled spectrophotometers and inexpensive computers in the 1990s has made diffuse reflectance measurements much more accessible.

3.1 Kubelka–Munk Theory

Figure 5 shows the essential elements of the Kubelka–Munk model for absorption and scattering of light. By definition, diffuse reflectance concerns light that penetrates the sample surface and can be absorbed by chromophores or scattered by internal surfaces. Specular or mirror-like reflectance must be excluded from the measurement. The sample is a composite of layers capable of both diffusely scattering and absorbing radiation, with the absorbors or chromophores uniformly distributed throughout the layers. The passage of light through the sample is described in terms of two fluxes: the incident light flux, $i$, which is normal to the sample surface, and the reflected light flux, $j$, which travels in the opposite direction. Reflectance is the ratio of the reflected flux to the incident flux, $j/i$, at the sample surface.

This model leads to two coupled differential equations, which can be solved for various boundary conditions. Details of this derivation are available in Kortum\(^{24}\) or Kubelka,\(^{22}\) Robinson\(^{25}\) has published a convenient summary of the Kubelka–Munk relations useful for the characterization of paper. For opaque samples (no
incident radiation passes through), the solution is the Kubelka–Munk remission function \( F(R_\infty) \), Equation (6). \( R_\infty \) is the reflectance of an opaque sample, \( k \) is the specific absorption coefficient and \( s \) is the specific scattering coefficient

\[
F(R_\infty) = \frac{k}{s} = \frac{(1 - R_\infty)^2}{2R_\infty} \tag{6}
\]

The specific absorption coefficient \( k \) is given by Equation (7)

\[
k(\lambda) = 2 \sum_i \epsilon_i(\lambda)C_i \tag{7}
\]

This quantity is analogous to the absorption coefficient of the Beer–Lambert law, that is the product of extinction coefficient and absorber concentration (the Kubelka–Munk relations reduce to the Beer–Lambert law in the limit of zero scattering). The linearity of Equation (7) is strictly valid in the limit of low absorption, just as the Beer–Lambert absorbance of solutions is linear with absorber concentration only at low absorbance.\(^{26}\)

Koukoulas and Jordan\(^{27}\) have shown that \( k \) is linear with absorber concentration over a range of about 60 m\(^2\) kg\(^{-1}\) (see section 3.2 for comments on the units of \( k \)). Polcin and Rapson determined that mechanical pulps obey Equation (7) well in the visible region.\(^{28,29}\) In the UV region, the strong absorption of lignin causes departure from strict linearity, but useful information regarding relative absorption changes and the position of absorption maxima can still be obtained.

It is clear from Equations (6) and (7) that chromophore concentration is not linear with respect to the observable quantity. \( R_\infty \), \( R_\infty \) is analogous to transmittance of transparent solutions and is sometimes plotted as \( \log(1/R_\infty) \) by analogy with the relationship between absorbance and transmittance in the Beer–Lambert law.\(^{26,30}\) Unlike the situation in solution, \( \log(1/R_\infty) \) is not linear with absorber concentration.

Equation (6) can be rearranged to express \( R_\infty \) as a function of \( k \). This is plotted in Figure 6, where \( s \) has been set to 30 m\(^2\) kg\(^{-1}\), a typical value of the scattering coefficient for high-yield pulps. The graphical presentation highlights an important consequence of the nonlinearity of the Kubelka–Munk equation: the effect of a change in absorption coefficient on reflectance depends strongly on the initial reflectance. A small change in absorption coefficient will affect a highly reflective sample substantially, but may have a minimal effect on a sample of low reflectance. As a later example will show, this can cause startling differences in the appearance of difference spectra, depending on how the raw data are presented.

The remission function, \( k/s \), is linear with respect to chromophore concentration if the scattering coefficient, \( s \), is constant. If this constraint is met, then differences in the remission function will be proportional to changes in the absorption coefficient and, hence, the chromophore concentration. However, in some samples of interest, e.g. pulps made from different refining processes, the scattering coefficients cannot be assumed to be constant. In this case, the absorption and scattering coefficients must be determined explicitly.

### 3.2 Equations for Determination of Absorption and Scattering Coefficients

While measurements of \( R_\infty \) can only be used to calculate the ratio \( k/s \), separate values of \( k \) and \( s \) can be obtained with an additional reflectance measurement and the use of Equation (8) (another of the equations derived by Kubelka and Munk).

\[
s = \frac{1}{b} \left( \frac{R_\infty}{1 - R_\infty} \right) \ln R_\infty \left( \frac{1 - R_\infty R_0}{R_\infty - R_0} \right) \tag{8}
\]

\( R_0 \) is the reflectance of a thin transmitting sample suspended over a black cavity of zero reflectance, \( b \) is the basis weight (mass per unit area) of the transmitting sheet. Once the scattering coefficient \( s \) has been calculated from Equation (8), the absorption coefficient can be calculated from Equation (6).

A note on units is required here. For most highly scattering materials, the sample thickness is used as the quantity \( b \) in Equation (8), which gives m\(^{-1}\) as the SI (System International) unit for absorption coefficient. However, paper samples are easily compressed and the sample thickness is not easily controlled. A more precisely defined property is the basis weight, or mass...
per unit area, usually specified in kg m⁻². Van den Akker²³ showed that basis weight can be used in the derivation of the Kubelka–Munk equations in place of path length with no loss in mathematical rigor. The SI unit for the absorption coefficient that results is m² kg⁻¹. Formally, values calculated this way are called specific absorption coefficients and specific scattering coefficients and lower case letters \( k \) and \( s \) are used in equations.

A problem of great interest in the chemistry of mechanical pulps is their rapid yellowing on exposure to UV light. This occurs only in the surface layers of a thick paper sheet, so that, after light exposure, the homogeneous distribution of chromophores needed for strict applicability of the Kubelka–Munk equations no longer holds. Absorption coefficients determined using Equations (6) and (8) under these conditions would not be linear with chromophore concentration.

Rigorous values for changes in \( k \) under such conditions can still be obtained using samples that are sufficiently thin so that a homogeneous chromophore concentration is maintained. This condition can be tested experimentally by determining that the reflectance is the same on both sides of the sample. In practice, samples with a basis weight in the range of 10–20 g m⁻² are sufficient. A procedure for preparation of such sheets is given in section 3.4.2. The suitability of these low-basis weight sheets is demonstrated visually by the scanning electron micrographs shown in Figure 7. These micrographs show cross-sections of a standard brightness sheet, basis weight 200 g m⁻² and a sample of 10 g m⁻² basis weight. The 10 g m⁻² sheet is, on average, no more than two fiber widths thick. Light from a modestly powered source will not be significantly attenuated on passing through such a sample.

Determination of \( k \) requires measurement of both \( R_0 \) and \( R_{wb} \), the reflectance of the sample when it is suspended over a highly reflective white backing of reflectance \( R_w \). \( R_\infty \) can then be calculated from another of the Kubelka–Munk relations, Equation (9).

\[
R_\infty + \frac{1}{R_\infty} = \frac{R_0 - R_{wb} + R_w}{R_w R_0} + R_{wb}
\]

Equation (9) is quadratic in \( R_\infty \), but one of the roots of the equation can be eliminated on physical grounds since \( 0 \leq R_\infty \leq 1 \). The scattering coefficient \( s \) is then calculated from Equation (8), and \( k \) is calculated from Equation (6).

### 3.3 Brightness and Its Relation to Reflectance Spectra

Brightness, or diffuse blue reflectance factor, is a standard industrial measurement of the whiteness of white or nearly white paper. It is, in essence, the reflectance of a fairly broad band of blue light from an opaque sample, measured under tightly prescribed conditions. Methods for the measurement of brightness and specifications for brightness measurement devices are published by several standard setting bodies: the Technical Association of the Pulp and Paper Industry (TAPPI) in the United States (T 452), the Pulp and Paper Technical Association of Canada (E.1), the Scandinavian Pulp and Paper Technical Association (SCAN C11:75), and the ISO (ISO 2470).

Jordan³¹ has given a comprehensive description of brightness measurement to which the reader is referred for detailed information.

Brightness is often referred to loosely as the reflectance measured at 457 nm and in research work such measurements from a scanning spectrophotometer are sometimes reported as equivalent to brightness. This procedure can lead to erroneous results, since the bandwidth of UV/VIS spectrophotometers is much narrower than the standard brightness filter.
An approximation of ISO brightness can be obtained from a reflectance spectrum by applying Equation (10),

$$\text{ISO brightness} = \sum_{\lambda} f(\lambda)R_{\infty}(\lambda)$$  \hspace{1cm} (10)

where $f(\lambda)$ is the spectral distribution function of a reflectometer equipped for measuring ISO brightness. Table 5 lists values of $f(\lambda)$ specified in ISO standard 2470 for the measurement of ISO brightness. These values include a normalization factor, so that brightness will be expressed as a percentage when $R_{\infty}$ is expressed as a fractional value. The response function should be chosen to correspond to the data interval of the spectral measurement.

Values obtained in this way cannot be called ISO brightness for contract verification or other commercial purposes and will not match exactly measurements from standard brightness measuring devices such as those available from Datacolor or Technidyne. This is because the exact requirements of integrating sphere geometry, illuminant and so on are not met. It is, however, an improvement over the procedure of single-wavelength measurements and will be useful to researchers who wish to relate their spectral results to this recognizable commercial scale.

As explained below, further caution is required when measuring samples that are known or suspected to contain fluorescent brighteners. Such materials absorb long-wavelength UV light (usually 340–400 nm) and re-emit it as blue fluorescence at $400 \text{ nm} < \lambda < 500 \text{ nm}$. Fluorescent brighteners are often added to paper to enhance whiteness. If samples are illuminated with a light source that is too rich in UV content the apparent brightness will be too high, owing to detection of fluorescent light as well as reflected light.

Standard brightness reflectometers use broad-band illumination of the sample. Reflected light is detected after it passes through a standard filter with the response function of Table 5. Alternatively, instruments of the abridged spectrophotometer type use a monochromator for detection and brightness is calculated by a microprocessor that applies Equation (10). To avoid excess excitation of fluorescence, ISO standard 2470 specifies that the light source in such instruments must be filtered to give a spectral distribution corresponding to the CIE (Commission Internationale d’Eclairage) C standard illuminant.

Scanning spectrophotometers use the opposite configuration of optical components, monochromatic illumination with broad-band detection. The above protocol for limiting UV content cannot be replicated with this type of instrument, so that ISO brightness calculated by applying Equation (10) to reflectance spectra will differ from standard measurements more for fluorescent samples than for nonfluorescent samples. It also follows from the above that reflectance measurements in the UV region could be substantially in error, since reflected and fluorescent light cannot be distinguished. The effect of fluorescence could be controlled with an instrument that uses both monochromatic detection and monochromatic illumination. An absorption spectrometer with this configuration (Bispectral Fluorescence Colorimeter, Labsphere, North Sutton, NH) has recently become commercially available.

#### 3.3.1 Postcolor Number

Giertz\(^{32}\) first proposed postcolor number, Equation (11), as a way to monitor the chromophores contributing to pulp brightness

$$\text{postcolor (PC) number} = [F(R_{\infty,1}) - F(R_{\infty,2})] \times 100$$ \hspace{1cm} (11)

$F(R_{\infty,i})$ is the remission function of Equation (6), calculated using standard brightness values in place of $R_{\infty}$. It has been used in many studies of chromophore changes that occur during bleaching or reversion of mechanical pulps.
Many standard pulp and paper laboratories do not have easy access to a spectrophotometer, but are equipped with a brightness-measuring device. In such cases, PC number is an appealing measurement. It is quick to do, and gives reasonably accurate estimates of the changes in absorption coefficient for samples where the process under study has not seriously affected the scattering coefficient or the homogenous distribution of chromophores throughout the thickness of the sheet.

A difficulty with PC number is that it reflects only absorption changes that occur in the region between 400–500 nm (see Table 5). However, many of the chromophores that are responsible for the yellowish cast of mechanical pulps have their strongest absorption in the near-UV region, 300–400 nm. This drawback to Equation (11) is easily remedied if, instead of using a brightness measurement for $R_{sc}$, an appropriate spectral measurement can be done. Most modern spectrophotometers have as part of the standard software package the ability to convert reflectance spectra to the corresponding remission functions.

Even when spectra are measured, the problems of using the remission function to compare samples where chromophores are not homogeneously distributed (e.g., light-induced yellowing), or where the samples have different scattering coefficients (e.g., pulps produced by different pulping processes) remain. In such cases, chemical changes can most confidently be studied by explicitly calculating $k$ and $s$ using the techniques described in section 3.2.

### 3.4 Instrumentation, Sample Preparation and Calculations

#### 3.4.1 Instrumentation

A scanning UV/VIS spectrophotometer with an integrating sphere attachment is required to measure reflectance spectra. Baseline stability is more difficult to maintain when doing reflectance measurements than with transmission measurements, so a double-beam instrument is strongly recommended.

Integrating sphere attachments have been available for many years from the manufacturer of Varian Cary and Perkin-Elmer instruments, and from Labsphere (North Sutton, NH), a specialist manufacturer of reflectance equipment. They are generally available in two size ranges: 6–7.5 cm in diameter and approximately 15 cm in diameter. Efficient functioning of the sphere requires that the sample port occupy only a small percentage of the internal surface area. For paper samples and particularly for the determination of $k$ and $s$ using thin sheets, larger spheres are preferred to lessen the effects of formation inhomogeneity.

As pointed out in section 3.1, specular reflectance must be excluded from measurements of diffuse reflectance. The area of the integrating sphere wall where specular reflectance from the sample falls is fitted with a removable attachment appropriate to the measurement being made. A glossy white plaque is used for measurements of total reflectance, while a black gloss trap is used for diffuse reflectance.

A computer is required to calculate $k$ and $s$, to average spectra, and to generate difference spectra. Modern spectrophotometers are equipped with a computer interface and have either a native language to manipulate spectra, or can export data to spreadsheets or widely usable formats (e.g., ASCII).

#### 3.4.2 Sample Preparation

Thin sheets that transmit some incident radiation to a background are required for the calculation in Equations (8) and (9). Because of the strong absorption of lignin, situations may arise through normal measurement error where $R_0$ equals or exceeds $R_{sc}$. Either of these conditions will lead to a singularity in Equation (8). Since the absorption of lignin becomes stronger as the wavelength is decreased from 400–300 nm, the thickness of the sample will determine the lower wavelength limit to which spectra can be measured. With practice, sheets of a basis weight as low as 10 g m$^{-2}$ can be made with the procedure shown below. Sheets of this basis weight allow reliable measurements to about 300 nm. Absorption coefficients can actually be obtained below 300 nm for sheets of this basis weight, however, the data tend to be noisy and should be interpreted with care.

Sheets of a basis weight as low as 10 g m$^{-2}$ can be prepared by the following procedure. Place a 74 µm Teflon® mesh over the wire of a static sheet-forming machine, taking care that no air bubbles are trapped between the mesh and the wire. Air bubbles will leave holes in the final sheet. Dilute an appropriate amount of pulp to obtain the desired basis weight to the full volume of the sheet machine and then filter onto the Teflon® mesh. Place the mesh and the sheet on a kraft blotter, mesh side down, and place an 18.5 cm diameter sheet of filter paper on top. Press the sheet manually with three or four passes of a couch roll. The Teflon® mesh can now be carefully peeled away, leaving the formed sheet on the filter paper. Place the sheet and filter paper sheet-side down on a stainless steel plate and press for 5 min at 0.34 MPa. After air drying, carefully separate the formed sheet from the filter paper with the aid of a spatula. This step is the most difficult and may require some practice. Mechanical pulps bleached with peroxide are easiest to work with, since several washing steps will have removed most of the sticky extractive material, and the exposure...
to alkali and peroxide creates anionic groups that aid fiber–fiber bonding. Unbleached pulps require the most care. Cut 5 × 5 cm² samples using a scalpel, being careful to avoid any holes that may have formed in the sheet. A rigid plastic template is useful here to obtain sheets of a known uniform area. Weigh the sheets and determine the basis weight.

A potential problem of using sheets of 10–20 m² kg⁻¹ basis weight is that formation of fibers into a sheet may be nonuniform over the area probed by a spectrophotometer beam. Averaging the results of three to six samples can minimize the error associated with this nonuniformity. In the author’s experience, standard deviations on the absorption coefficients vary from a maximum of 5–10% at wavelengths below 300 nm to 1–2% at wavelengths above 300 nm.

### 3.4.3 Calculations

Some spectrophotometers report reflectance measurements as percentage values. In Equations (6), (8) and (9) the reflectance values must be fractional. Because of the nonlinear nature of these equations, factors of one hundred will not cancel simply.

Once the raw data (\(R_{ab}, R_{wb}, R_\gamma, b\)) has been collected, the calculation of Equations (9), (8) and (6) (in order) are done to determine the absorption and scattering coefficients. Some spectroscopic software packages have a native programming language that will allow this type of manipulation, as well as averaging and subtraction of spectra. Otherwise, the data can be exported to a spreadsheet program or transmitted as ASCII characters and manipulated by user-written software.

Lignin contains many overlapping UV absorptions and plots of \(k\) versus \(\lambda\) will usually show steadily increasing absorption on going from 400–300 nm, with no discrete absorption maxima. Subtraction of the appropriate spectra to generate difference spectra will usually reveal maxima that are characteristic of the chromophore changes occurring (see section 3.6).

### 3.5 Major Chromophores in Mechanical Pulps

#### 3.5.1 Coniferaldehyde

Coniferaldehyde end groups (second entry in Table 4) are responsible for some of the yellowish tint of softwoods.\(^{133}\) The longest wavelength maximum for etherified coniferaldehyde model compounds occurs at around 340 nm. Although this is below the visible region, the band is very broad and there is nonzero absorption at wavelengths as high as 430 nm. This is sufficient for this group to contribute to ISO brightness, since the spectral distribution function (see Table 5) has finite values to wavelengths as low as 400 nm.

#### 3.5.2 Biphenyls

Soluble lignins and biphenyls have much shallower minima at 250–270 nm than the monomeric lignin-like phenols. Pew and Connors\(^{34,35}\) prepared a number of \(o\)-\(o\)-dihydroxybiphenyl derivatives by dehydrogenative coupling of simple guaiacyl phenols, and concluded that much of the difference between the spectra of lignins and monomeric phenols could be accounted for by the presence of a substantial number of biphenyl structures in lignin. The work by Karhunen et al.,\(^{4–6}\) which reports substantial amounts of biphenyl groups bonded in dibenzodioxin structures (Figure 2), would appear to be consistent with this view.

#### 3.5.3 Quinones

Quinones have long been considered to be contributors to the color of wood and high-yield pulps.\(^{36–38}\) \(\alpha\)-Quinones, in particular, are invoked in many reaction schemes purporting to explain pulp bleaching reactions, as well as reactions proposed to explain darkening under the influence of heat or light.\(^{39}\)

Generally, \(p\)- and \(\alpha\)-quinones each show three characteristic bands, although the weaker bands are sometimes obscured under the stronger ones.\(^{40,41}\) Table 6 shows the general characteristics of \(p\)- and \(\alpha\)-quinones and the band assignments, while Table 7 gives specific data on some quinones of relevance to lignin. The differences between \(\alpha\)- and \(p\)-quinones are readily apparent to the eye; \(\alpha\)-quinones are yellow, while \(p\)-quinones tend to be dark red.

Imsgard et al.\(^{44}\) determined that spruce milled-wood lignin contained 0.7% \(\alpha\)-quinone structures by reducing the quinones to the corresponding catechols and then measuring the visible spectrum of the complex formed between the catechols and ferric ion. This agrees well with other values in more recent literature. Zakis\(^{45}\) found 0.8% \(\alpha\)-quinones in spruce milled-wood lignin, based on the ability of quinones to oxidize hydrazine and release a stoichiometric amount of nitrogen. Argyropoulos and

</table>

Heitner$^{[46]}$ found 0.7% $o$-quinone groups in black spruce TMP, based on $^{31}$P NMR spectra of the trimethyl phosphite–quinone adducts.

The spectra of $o$-quinones with an adjacent methoxy group exhibit an unusual solvent effect. In nonaqueous solvents, these compounds show a prominent maximum at approximately 480 nm. In an aqueous solvent, the absorption at 480 nm is diminished, and a second more intense maximum appears at about 370 nm. Adler et al.$^{[42]}$ attribute this behavior to an equilibrium between the $o$-quinone and a monohydrate adduct.

3.5.4 Metal Complexes

Spruce milled-wood lignin contains, in addition to 0.7% quinone groups, 1% catechol groups.$^{[44]}$ Lignin catechols form complexes with ferric ions with a broad absorption from 470–700 nm, $\lambda_{\text{max}}$ around 560–800 nm, and $\varepsilon$ in the
range $1–2 \times 10^3 \text{L mol}^{-1} \text{cm}^{-1}$. Ferric and ferrous ions also form complexes with other lignin structures such as phenols and biphenyls. However, the extinction coefficients for these complexes are 10–100 times smaller than those of the catechol complexes. Other common metal ions (Cu$^+$, Mn$^{2+}$, Zn$^{2+}$) have little effect on the color of high-yield pulp fibers.

3.5.5 Hydrogen-bonded Complexes

There are sporadic reports suggesting complex formation between different lignin structures as a source of color. The color of kraft lignin has been attributed both to quinhydrones, donor–acceptor complexes between a quinone and a hydroquinone, and to quinone–phenol complexes. Such complexes are held together by hydrogen bonds and can be particularly strong in the solid state. They often have an intense visible absorption due to a charge-transfer transition.

The spectra of simple o- and p-quinones adsorbed on high-yield pulps have been recorded. Table 8 compares these spectra with the corresponding spectra in solution. For the o-quinones in particular, the solution spectra are significantly different from those recorded when the compound was adsorbed on high-yield pulp. These few observations might be consistent with the formation of complexes between the added quinones and phenol, catechol or other donor groups in the lignin. However, much more systematic work is required before concluding that these observations cannot be explained in terms of the red shifting and band broadening that are usually expected for electronic spectra in the solid state.

3.6 Sample Spectra

The key to effective and efficient use of reflectance spectroscopy when studying chromophore chemistry is to understand the limitations of each of the ways of obtaining and presenting data, and to match this to information that is required from the experiment. Two examples are presented here; others are summarized elsewhere.

3.6.1 Difference Spectra for Peroxide Bleaching

Alkaline hydrogen peroxide is an effective bleaching agent for mechanical pulps and much effort has been expended to understand the nature of the chromophores involved in the bleaching reactions. Figure 4 shows the reflectance spectra obtained for opaque samples of black spruce TMP before and after peroxide bleaching. The spectra show clearly that the bleached sample has a significantly higher reflectance at all wavelengths and that for both samples reflectance drops rapidly for $\lambda < 400$ nm. No information with respect to absorption maxima is evident for spectra presented in this way.

Figure 8(a) shows the differences in $R$ ($\infty$) for the two pulps, $\Delta R$ ($\infty$) = $R$ (bleached) $- R$ (unbleached). Two maxima, each corresponding to a reflectance increase of approximately 0.2, appear at 380 nm and 480 nm. This differs sharply from the spectrum in Figure 8(b), the difference in absorption coefficients, $\Delta k = k$ (bleached) $- k$ (unbleached), for the same two pulps. A strong bleaching with $\lambda_{max} = 360$ nm occurs in the UV. There is a general decrease in the absorption coefficient in the visible region, but there is no clear absorption maximum. While the changes in $R$ ($\infty$)
MECHANICAL PULPS, ULTRAVIOLET/VISIBLE SPECTROSCOPY OF CHROMOPHORES IN

\[
\Delta R_\infty = R_{\infty, \text{bleached}} - R_{\infty, \text{unbleached}}
\]

\[
\Delta k = k_{\text{bleached}} - k_{\text{unbleached}}
\]

at 480 nm and 380 nm are almost equal, the changes in \(k\) at these two wavelengths differ by about a factor of eight.

The reason for the startling differences between spectra of \(\Delta R_\infty\) and \(\Delta k\) is the nonlinearity of \(R_\infty\) with respect to \(k\), shown earlier in Figure 6. Recall that Figure 6 was computed assuming a typical value of \(s\) for mechanical pulps, of 30 m\(^2\) kg\(^{-1}\). At 480 nm, the reflectance of the unbleached pulp is about 0.55, and a decrease in \(k\) of 10 m\(^2\) kg\(^{-1}\) is sufficient to cause an increase in reflectance of 0.2. At 380 nm, where the initial reflectance is only about 0.12, \(k\) must decrease by about 80 m\(^2\) kg\(^{-1}\) to achieve a reflectance increase of 0.2.

The two major chromophores removed in peroxide bleaching are coniferaldehyde (\(\lambda_{\text{max}} = 360\) nm) and \(\alpha\)-quinones.\(^{38}\) \(\alpha\)-Quinones may also be removed, although the evidence for their presence in native lignin is less clear. \(\alpha\)-Quinones have very broad absorption bands with \(\lambda_{\text{max}}\) in the region of 480 nm (see Table 7), although the intensity of this band may be diminished somewhat in the presence of water (section 3.5.3).

The absorption due to coniferaldehyde is quite strong and tails well into the visible region. This probably accounts for the inability to see a discrete peak due to \(\alpha\)-quinones in the spectrum of \(\Delta k\); the broad \(\alpha\)-quinone absorption is probably merged with the tailing coniferaldehyde absorption. Note that the absorption of \(\alpha\)-quinones, already broad in solution, is even broader where the \(\alpha\)-quinones have been generated in high-yield pulp. This can be achieved by the reaction of Fremy’s salt, potassium nitrosodisulfonate, with lignin phenolic groups.\(^{43,53,57}\)

The above suggests that spectra of \(\Delta R_\infty\) more effectively reveal the appearance or disappearance of weak peaks in the visible region. However, one should also note that the position of \(\lambda_{\text{max}}\) can differ substantially between these two presentations, at least in the UV region. Thus, while the spectrum of \(\Delta R_\infty\) shows a maximum at 380 nm, the spectrum of \(\Delta k\) shows a maximum at 360 nm. The absorption maximum observed for \(\Delta k\) is red shifted by about 20 nm from the value observed for etherified coniferaldehyde in solution (Table 4), a value that can reasonably be explained in terms of red shifting in the solid state. Thus, it is more likely to be the correct absorption maximum than that observed for \(\Delta R_\infty\).

3.6.2 Difference Spectra for Light-induced Yellowing

A second example is taken from work on the light-induced yellowing of mechanical pulps. It illustrates the profound effect that residual amounts of a chromophore can have on absorption difference spectra.

Figure 9 shows the absorption difference spectra observed for UV irradiation of two samples of peroxide-bleached black spruce TMP.\(^{58}\) The sample in Figure 9(a) was bleached with a single, 3% charge of hydrogen peroxide. This amount of peroxide is typical in the industrial production of mechanical pulps with an ISO brightness in excess of 70%.

Alkaline hydrogen peroxide reacts quantitatively with coniferaldehyde model compounds within minutes.\(^{59}\) However, several studies have shown that the reaction...
The marked difference between the two sets of difference spectra in Figure 9 occurs because coniferaldehyde is bleached by UV light. The spectra in Figure 9(b) show a dominant absorption increase at 360 nm, with a shoulder at 416 nm. The spectra in Figure 9(a) show instead absorption maxima at 330 nm and 416 nm, and a minimum at 360 nm. Photobleaching of coniferaldehyde has slowed the overall absorption increase at 360 nm sufficiently to show that there are smaller independent increases in absorption, with \( \lambda_{\text{max}} \) at about 330 nm and 416 nm.

These spectra indicate that the irradiation of mechanical pulps produces at least three different chromophores. The peak in the visible region with \( \lambda_{\text{max}} \) at about 416 nm is usually attributed to photochemical formation of \( \alpha \)-quinones. Clear evidence for this proposition is the observation of \(^{31}\text{P} \) NMR signals for \( \alpha \)-quinone–trimethylphosphate adducts. Difference spectra for irradiation of pulps reduced with sodium borohydride indicate that the 330 nm arises from oxidation of benzyl alcohol groups in the pulp to the corresponding aldehydes or ketones. There is less clear evidence for the identity of the chromophore responsible for the strong absorption increase at 360 nm. Recent phloroglucinol staining experiments suggest that \( \rho \)-quinones are likely candidates.

3.6.3 Color Tests

Nakano and Meshitsuka have described a number of color-forming reactions for lignin and specific lignin structures. Of these, the phloroglucinol reaction (Wiesner reaction) is the most widely used and will be described briefly here.

Coniferaldehyde residues react with acidic alcoholic solutions of phloroglucinol (1,3,5-trihydroxybenzene) according to the reaction in Figure 10 to give an intensely red complex with \( \lambda_{\text{max}} = 550 \) nm. The reagent is prepared very simply by mixing two volumes of a 2% ethanolic solution of phloroglucinol with one volume of concentrated hydrochloric acid. Since the reagent is not very stable, the phloroglucinol solution is stored in the dark and is mixed with the acid immediately before use. The color reaction is instantaneous upon placing a drop of the solution onto a sample. Because of its sensitivity and ease of use, this reagent is often used by papermakers to test for the presence of mechanical fiber in paper.

Davidson et al. reported the difference spectra of spruce wood sections and bleached softwood mechanical pulp that had been irradiated and then stained with phloroglucinol. The irradiated and stained samples showed an absorption increase with \( \lambda_{\text{max}} = 550 \) nm, which they attributed to photochemical formation of coniferaldehyde. However, in a subsequent publication, they
found that phloroglucinol also gives a similar color reaction with methoxy- \( p \)-quinone, which would seem more consistent with the behavior of coniferaldehyde reported in section 3.6.2.

### 4 OTHER TECHNIQUES

#### 4.1 Derivative Spectroscopy

Derivative spectroscopy is used to resolve more of the fine structure in a spectrum known or suspected to consist of several overlapping bands. The absorbance or reflectance is plotted as the second derivative with respect to wavelength. Spectral features accentuated as higher derivatives are taken, at the expense of increased noise in the spectrum. Lin applied the technique to soluble lignins\(^{(65)}\) and found that the absorption due to added phenol in a solution of lignosulfonate can be accurately resolved and quantified. However, a significant limitation of derivative spectroscopy when applied to soluble lignins is that it cannot resolve absorptions in the important region between 300 and 400 nm.

Derivative spectroscopy can also be applied to diffuse reflectance spectra, although only one report has appeared in the literature. Michell et al.\(^{(66)}\) were able to resolve some spectral features in the 300–400 nm region in a study of bleaching and yellowing of mechanical pulps from *Eucalyptus regnans*.

#### 4.2 Transient Spectroscopy

Transient spectroscopy is the extension of difference spectroscopy to very short timescales, so that short-lived chemical species can be monitored. The absorbance or reflectance of the sample is measured before and after a brief, intense light pulse strikes the sample, generating a significant population of excited states, and/or reactive intermediates. The excitation source is usually a pulsed laser. In absorbance mode, the data are handled exactly as described in Equations (3–5) of section 2.3.3. The technique has only recently been extended to measure reflectance from opaque samples. More detailed information on transient absorbance measurements is available in a review by Hadel\(^{(67)}\) and information on transient reflectance measurements is available in a review by Wilkinson and Kelly\(^{(68)}\).

The transient absorbance experiment has been applied both to studies of lignin model compounds\(^{(69)}\) and to soluble lignin preparations.\(^{(70)}\) Guaiacyl-like aromatic ketones (e.g. 3,4-dimethoxyacetophenone) show unusual photophysical behavior. In most acetophenones, the initially formed first excited singlet state is converted to the lowest triplet state with 100% efficiency and all photochemical reactions occur from the triplet. In contrast, triplet-quenching studies indicate that chemistry can occur from both the singlet and triplet states in lignin ketones.\(^{(71)}\)

Diffuse reflectance transient spectroscopy has been used to study the reactive intermediates in the photoyellowing of mechanical pulp.\(^{(72,73)}\) A transient absorption was observed with \( \lambda_{\text{max}} \) at about 450 nm and was identified as a carbonyl triplet state based on two experimental observations, quenching by oxygen and an increase in absorption intensity when phenolic groups were etherified. Both oxygen and phenols quench carbonyl triplet states.

Chemical analysis plays an important role in pulp and paper research and in the day-to-day operation of pulp and paper mills. It is used in practically every aspect of the papermaking process, including the characterization of raw materials and products, optimization of process parameters, addressing environmental concerns, and diagnosing operation and product quality problems. This article provides an overview of the major types of chemical analyses performed on pulp and paper matrices. The emphasis is mainly on the principle, significance, and applications of the various analyses. Details of analytical techniques and instrumentation can be found in specialized textbooks on the subject and in the references provided in each section. It is assumed that the reader is somewhat familiar with the basic terminology and processes involved in pulp and paper manufacture. If this is not the case, the reader is advised to consult some of the many excellent references on the subject.

2 APPLICATIONS OF CHEMICAL ANALYSIS IN THE PULP AND PAPER INDUSTRY

Practically every aspect of the pulp and paper-making process relies on the use of certain types of chemical analyses. The majority of these analyses fall into one of the following areas of applications:

- To characterize raw materials and products. The principal raw material is wood. Depending on the particular end-use, several factors such as lignin content, type and amount of carbohydrates, extractives content and composition may have to be determined to assess their effect on pulping conditions and on the quality and properties of the final product. Products may be broadly classified into wood pulp, paper, and board. Chemical analyses are commonly performed on pulp, either bleached or unbleached. These must often be characterized for a number of parameters, including lignin content, viscosity, carbohydrate level, extractives content and composition, and metal profile. Many of the tests performed on pulp are also applicable to paper and board products. Both of these end products, however, are also tested for the level and composition of various additives such as fillers, coatings, and sizing agents.

- To establish and optimize process parameters. During pulp manufacture, analyses of pulping liquors are carried out frequently to monitor the concentration of active components in these liquors and adjust the pulping conditions accordingly. Unbleached pulp...
and also bleaching liquors must be characterized in order to control the charge of bleaching chemicals. In the kraft recovery process, pulping and spent liquors are analyzed on a regular basis to determine the level of makeup chemicals that must be used in the system.

- To address environmental concerns. A wide range of analyses are performed regularly on effluents and receiving waters from pulp and paper mills to monitor various parameters such as organic content, level of specific pollutants, color, and toxicity, and to ensure that environmental regulations are being met.

- To diagnose operation and product quality problems. Chemical analysis often provides a valuable tool to diagnose various mill problems. Typical operation problems may include incomplete combustion of black liquors, or black-outs, in kraft recovery boilers, pitch deposits, scaling, or corrosion of process equipment, to mention only a few. Problems involving product quality often involve contamination of the finished product with dirt specks which can downgrade its quality and cause a loss of production. In many cases, application of selected chemical analyses can help to establish the cause of the problem and in devising suitable means of resolving them.

### 3 TEST METHODS

Based on the foregoing, it is evident that a variety of chemical analyses are required to characterize wood, pulp, paper, and process liquors and to determine their properties for a diversity of end-uses. Accordingly, a large number of test methods have been developed over the years for mill applications and for research purposes. Many of these analyses, particularly those that are commonly used in mills, have been adopted as standards or official test methods by a number of organizations worldwide. A list of major pulp and paper standards organizations is shown in Table 1.

### 4 PRINCIPAL COMPONENTS OF WOOD

In order to appreciate better the significance of chemical tests conducted on pulp and paper matrices, it is appropriate first to review the chemical composition of the starting raw material, namely wood.

As shown in Table 2, wood is made up of several components, including cellulose and hemicelluloses, which together comprise the holocellulose or carbohydrate fraction of wood, lignin, extractives, and inorganics.

#### 4.1 Cellulose

This is the main component of wood, making up 40–50% of its weight. Cellulose consists of a straight or linear polysaccharide chain made up of anhydro glucose units connected with each other by 1→4-β-glucosidic linkages to form a continuous linear chain (Figure 1). Cellulose has a partially crystalline structure with a degree of polymerization (DP) ranging from 7000 to 10000, depending on its source and method of isolation. One of its important chemical properties is its resistance to alkalis, most acids, and organic solvents. It is, however, readily degraded by concentrated sulfuric acid, and this property is commonly used to separate it from lignin.
4.2 Hemicelluloses

These are polysaccharides of considerably lower molecular weight than cellulose, making up 15–20% of the weight of coniferous wood (softwoods) and 20–35% of deciduous wood (hardwoods). Unlike cellulose, which is linear, hemicelluloses are made up of branched chains consisting of glucose, xylose, mannose, arabinose, and galactose units. In softwoods, the major hemicellulose sugars are mannose and xylose, whereas in hardwoods, xylose predominates. The DP of hemicelluloses is considerably lower than that of cellulose, typically ranging between 50 and 300. They are largely soluble in aqueous alkali solutions, and are readily degraded by acids.

4.3 Lignin

The content of lignin in softwoods varies between 23 to 33% and in hardwoods between 16 and 25%. Lignin has a highly aromatic branched chain structure, consisting mainly of phenylpropane units with aryl ether and alkyl linkages. Its molecular weight varies greatly, depending on the method of isolation, ranging from 2000 to $10^6$. One of the important properties of lignin is that it is essentially insoluble in concentrated sulfuric acid. In its native form, it is almost insoluble in organic solvents.

4.4 Extractives

These are relatively low molecular weight substances generally making up 2–10% of the weight of wood. As their name implies, extractives are mostly soluble in a variety of organic solvents; the most commonly used ones are ethanol–benzene (1:2), dichloromethane, acetone, chloroform, and diethyl ether. The major classes of wood extractives include the terpenes, polyphenols, including flavonoids and lignans, and resins such as fatty and resin acids, glycerides, waxes, and sterols. Certain types of extractives, such as tannins, gums, sugars, and starches, are water soluble.

4.5 Inorganics

Inorganics usually make up 0.2–3% of wood, depending on species. Most North American wood species have an ash content below 1%. The major inorganic components of wood are calcium, potassium, and magnesium, present mainly as silicates, phosphates, or sulfates. Several minor elements are also present including, iron, manganese, sodium, chlorine, and aluminum.

Depending on the type and extent of treatment to which the wood is subjected during pulping, bleaching, refining, or other paper-making processes, there is a certain degree of removal, degradation, or chemical modification of some of these wood components. Accordingly, many of the chemical tests performed on wood pulp are aimed at determining, either directly or indirectly, the extent of these changes by measuring the amount and chemical nature of these various components.

The next section examines the various methods and techniques commonly used for the characterization of wood pulp. Subsequent sections will deal with the analysis of process liquids, paper, and deposits and contaminants. Standard PAPTAC and TAPPI test methods are mentioned in the text, as appropriate. Related methods from other standard organizations (e.g. ISO, SCAN, APPITA, and ASTM) can be found in the corresponding PAPTAC or TAPPI methods.

5 CHEMICAL CHARACTERIZATION OF WOOD PULP

The major types of wood pulp manufactured by the pulp and paper industry are listed in Table 3. These can be broadly classified as mechanical, chemimechanical, semichemical, or chemical. As indicated in Table 3, each type can be further subdivided into several classes to reflect more specifically the process used in the mill. Certain tests are only applicable to chemical pulps, while others are intended for all types of pulp.

5.1 Determination of Carbohydrates

Several tests are commonly performed in pulp mills to monitor the degree of cellulose and hemicelluloses removal or degradation during pulping and bleaching. These changes can affect the quality of the pulp, particularly its strength properties. Minimum loss of these components is desirable in order to preserve pulp yield and to achieve optimum papermaking properties. For example, a high retention of hemicelluloses during
pulping is associated with improved beatability of the pulp, which in turn results in higher tensile strength.

In process control applications, the most widely used methods for evaluating the level or extent of degradation of carbohydrates are based on the determination of pulp viscosity, alkali solubility and pentosan content. These will be considered first. For more detailed carbohydrate profiles and molecular weight distributions, both of which are often required in pulping and bleaching research, several instrumental methods have been developed and will be subsequently described.

5.1.1 Pulp Viscosity

The viscosity of a pulp is related to the DP of the cellulose, and therefore, indicates the extent of its degradation. The more commonly used standard test for measuring pulp viscosity is applicable only to the bleached or delignified pulp with a lignin content below 4% (PAPTAC G.26; TAPPI T223). The test involves dissolving a pulp specimen in cupriethylenediamine (CED) – a solvent specific for cellulose – and measuring the viscosity of the resulting solution with a capillary viscometer. If the lignin content is higher than 4%, the sample must first be delignified with a sodium chlorite–acetic acid solution prior to viscosity measurement (PAPTAC G.10U). The average DP of cellulose can be estimated from calculated intrinsic viscosity values (SCAN C15). Comparison between several methods for determining pulp viscosity and conversion between DP and intrinsic viscosity have been reported by Sihtola et al. (9)

5.1.2 Alkali Solubility

Several tests are used to determine the solubility of pulp in various alkali solutions, as a measure of cellulose and hemicellulose removal or degradation. Extraction of wood or pulp in hot 1% sodium hydroxide removes hemicelluloses and degraded cellulose (PAPTAC G.6 and G.7; TAPPI T212). Degraded cellulose represents the portion of the original cellulose which has been broken down into lower molecular weight fragments during pulping or bleaching. This test is applicable to all types of samples, including wood and chemical or mechanical pulp. The following tests are generally applicable only to bleached or delignified pulp.

10 and 18% alkali solubility (PAPTAC G.26; TAPPI T235): in this test, a pulp sample is extracted with a 10 or 18% sodium hydroxide solution at 25°C and filtered. The dissolved organic matter in the filtrate is determined by oxidation with potassium dichromate, followed by titration of the excess dichromate with ferrous ammonium sulfate. Both degraded cellulose and hemicelluloses are removed in 10% sodium hydroxide: at this alkali concentration, swelling of cellulose fibres is at a maximum. At 18% sodium hydroxide concentration, limited amounts of degraded cellulose are removed, and the dissolved material consists mainly of hemicelluloses. It must be emphasized that the solubility in these alkali solutions does not represent the total hemicelluloses or cellulose content of a pulp; it is only a measure of hemicelluloses or degraded cellulose that can be dissolved under the conditions of this test.

α-, β-, and γ-cellulose (PAPTAC G.29; TAPPI T203): this test provides an indication of hemicellulose retention in pulp during pulping and bleaching. The standard test for determining pentosans is applicable to wood, and to all types of pulps, and consists of hydrolysis of the pentosans in the sample to furfural using boiling hydrochloric acid, followed by distillation and colorimetric determination of furfural with orcinol–ferric chloride (PAPTAC G.12; TAPPI T223). The test, however, provides a better indication of hemicellulose content in hardwood pulp, since softwood hemicelluloses consist of a mixture of pentose and hexose units, whereas hardwood hemicelluloses are mainly made up of pentoses. The use of orcinol to determine total carbohydrates in pulp leachates was also

reported by Willis et al. Standard sugar solutions were used to calibrate the method. Appropriate correction factors were applied to account for the absorbance due to lignin. Provided that independent calibration curves are obtained for each type of sample, this technique could be used as a rapid method for determining total carbohydrates in pulp filtrates and in process liquids.

5.1.4 Detailed Carbohydrate Profiles

The test methods described so far are particularly useful for estimating the proportions of various carbohydrate fractions in pulp. However, a detailed profile of the type and amounts of individual monosaccharides can also be required. A large number of publications has dealt with the determination of monosaccharides in wood and pulp. This is generally accomplished by hydrolysis of the sample, followed by separation of monosaccharides using one of several chromatographic techniques.

The hydrolysis is generally carried out by a two-step procedure with sulfuric acid (TAPPI T249). Primary hydrolysis is performed at 30°C for 1 h. This is followed by dilution of the sample and a secondary hydrolysis step at 120°C. The samples are then neutralized before analysis. An alternative hydrolysis procedure involves the use of trifluoroacetic acid (TFA). The advantages of using TFA are shorter reaction times and no need for neutralization of the sample since TFA can be removed by evaporation. The drawback of using TFA is that, for samples with higher lignin contents, there may be incomplete hydrolysis. If longer hydrolysis times are used, sugar degradation may occur and therefore correction values must be applied to the results.

After hydrolysis, the sugars can be analyzed by various chromatographic procedures. Paper chromatography was used for many years, but has now been largely replaced by gas or liquid chromatography. In gas chromatography (GC), the monosaccharides can be derivatized prior to analysis. The more common derivatives are alditol acetates, which are prepared using sodium borohydride as a catalyst during acetylation. This lengthy derivatization procedure has been considerably shortened with the use of 1-methylimidazole as a catalyst during acetylation. Monosaccharides can also be converted to trimethylsilyl (TMS) derivatives. Although this is a faster procedure than alditol acetate derivatization, the chromatograms are considerably more complex, since several peaks are produced for stable isomers of each neutral sugar.

High-performance liquid chromatography (HPLC) is also widely used for determination of monosaccharides in wood and pulp hydrolyzates. In HPLC analysis, derivatization is not required, and consequently the analysis time is considerably shorter than with GC analysis. Although most of the earlier HPLC analyses were based on refractive index (RI) detection, more recently, the use of high-performance anion-exchange chromatography (HPAEC) columns coupled with pulsed amperometric detection (PAD) has been reported by several workers. The major advantages of PAD are its linearity over a much wider range of sugar concentration and higher sensitivity compared with RI detection. Figure 2 shows a typical HPAEC/PAD trace for an unbleached kraft pulp hydrolyzate, obtained using a Carbopac ion-exchange column. The high selectivity achieved with this type of column is clearly evident. In spite of the high glucose level present in the sample, the adjacent galactose peak is well resolved.

The chromatographic methods described above allow the determination of the five major monosaccharides originating from the holocellulose (cellulose and hemicelluloses) fraction of wood and pulp. In order to determine the amount of cellulose and hemicelluloses separately, it is necessary to estimate the glucose contribution to the hemicelluloses. This contribution can be calculated from a ratio of mannose to glucose of 3:1 for softwoods and 2:1 for hardwoods. The cellulose fraction can then be calculated by difference between total glucose and that associated with hemicelluloses.

One of the drawbacks of sulfuric acid hydrolysis is that only neutral sugars can be determined by this approach. Sugar acids, such as galacturonic acid, which are formed during kraft pulping, are usually degraded during this treatment. This problem can be overcome through the use of enzymatic hydrolysis. Using a commercial enzyme mixture for hydrolysis, followed by HPAEC/PAD, monosaccharides and sugar acids, including 4-O-methylglucuronic and hexenuronic acids, were determined in several types of laboratory and mill kraft pulp. Another method which was found suitable for quantifying sugar acids involves the use of acid...
methanolysis.\(^{25}\) Hydrolysis was carried out in a mixture of hydrochloric acid in anhydrous methanol. This was followed by silylation and analysis of sugars by GC. Figure 3 shows a gas chromatogram of silylated sugar units obtained after acid methanolysis of TMP fibers.\(^{25}\) All sugar components, including uronic acids, are well resolved. The peaks were identified by gas chromatography/mass spectrometry (GC/MS) and by analyzing acid methanolysis products of analytical-grade sugars. One of the advantages of this approach is that cellulose is not degraded significantly during methanolysis. Hence only the noncellulosic glucose, originating from hemicelluloses, can be measured.

More recently, capillary electrophoresis (CE) was used for the separation and quantitation of neutral and acidic mono- and oligosaccharides in wood-derived hemicelluloses.\(^{26}\) Mono- and oligosaccharides were derivatized by reductive amination with 6-aminoquinoline, and separated as their borate complexes by capillary zone electrophoresis (CZE). High sensitivity was achieved with on-column ultraviolet (UV) detection at 245 nm.

5.1.5 Molecular Weight Distribution of Carbohydrates

One of the common approaches for determining molecular weight distribution of pulp holocellulose is by size-exclusion chromatography (SEC) of their tricarbanilate derivatives.\(^{27,28}\) Holocelluloses are derivatized with phenyl isocyanate in the presence of pyridine, as a solvent and catalyst, to form the cellulose tricarbanilate (CTC). The CTC is recovered from the pyridine solution by precipitation in a nonsolvent. SEC is then performed with tetrahydrofuran (THF) as eluent using SEC columns of different pore size connected in series. The advantage of this derivatization procedure is that it leads to complete trisubstitution of cellulose with minimum degradation. It was shown, however, that the loss of the low molecular weight fraction could occur during the reprecipitation step.\(^{29}\) and must be accounted for by performing the SEC analysis on both the soluble and insoluble fractions.

A relatively new technique, matrix-assisted laser desorption/ionization time-of-flight (MALDI/TOF) mass spectrometry (MS) has also been applied to the determination of the molecular weight distribution of carbohydrates. The principle of this technique was recently reviewed by Harvey.\(^{30}\) Samples are diluted with a suitable matrix and ionized by irradiation with a laser. Desorbed ions from the vaporized sample are then detected by MS. The technique was used by Dahlman et al.\(^{31}\) to determine the molecular weight distribution of oligosaccharides in hardwood kraft pulp. The main advantages of this technique are its high sensitivity, wide mass range, simple sample preparation, and no fragmentation of the molecules analyzed.

5.2 Determination of Lignin

This is undoubtedly one of the more important tests on chemical pulp, since the main goal of chemical pulping is to remove the lignin from the wood with minimum degradation of the carbohydrates. Consequently, one of the major objectives of measuring lignin is to assess the effect of a particular pulping or bleaching process on the degree of delignification. Another important purpose is to determine bleaching requirements. The higher the level of residual lignin in unbleached pulp, the greater the amount of bleaching chemicals that must be applied in order to achieve a target brightness.

Comprehensive textbooks and reviews have been written on lignin chemistry and on methods of lignin determination.\(^{1,32,33}\) Lignin content can be determined by both direct and indirect methods. By far the most widely used direct method is the so-called Klasson lignin determination, in which the lignin is measured gravimetrically (PAPTAC G.8 and G.9; TAPPI T222). In this method, a sample of 1–2 g of finely ground and pre-extracted wood or pulp is treated with 72% sulfuric acid at room temperature for 2 h, diluted with water, and then boiled for 4 h to hydrolyze and solubilize the carbohydrates completely. The residue, after filtration, is weighed and is referred to as acid-insoluble or Klasson lignin. A modified procedure for smaller samples (200 mg) was reported by Efland.\(^{34}\) A small portion of lignin

![Figure 3](image-url)
is dissolved during acid hydrolysis. This acid-soluble lignin is determined spectrophotometrically, from the UV absorbance at 205 nm of the filtrate from the Klason lignin determination (PAPTAC G.8 and G.9; TAPPI UM250). The amount of acid-soluble lignin varies from less than 1% in softwoods and Kraft pulps to 1–4% in most hardwoods. The acid-soluble lignin content in groundwood and high-yield pulp is similar to that of the original wood. The total lignin content is determined from the sum of the acid-insoluble and acid-soluble lignin in the sample.

Among the most widely used indirect methods are those based on oxidation of lignin with potassium permanganate (PAPTAC G.18; TAPPI T236), or chlorination with sodium hypochlorite (PAPTAC G.32; TAPPI T253). In the former procedure, a pulp sample is treated with an acidified potassium permanganate solution. The excess permanganate is determined by titration with sodium thiosulfate after addition of potassium iodide. The permanganate consumed in the reaction is related linearly to the lignin content and expressed as “kappa number”. This test is mostly applicable to chemical and semichemical pulps with a yield below 70%. It is not applicable to mechanical or high-yield pulps because the lignin in such pulp is not completely oxidized by the permanganate. For conventional Kraft and sulfite pulps with yields below 70%, the relationship between kappa number and Klason lignin is essentially linear and given by Equation (1):

\[\text{kappa number} \times 0.15 = \text{Klason lignin} \quad (1)\]

A similar principle is used in pulp chlorination, except that in this case the sample is treated with a sodium hypochlorite solution, and the result is expressed as the “hypo number”. Unlike the kappa number, the hypo number test is applicable to all types and grades of pulp, including high-yield pulps. The relationship with lignin was also found to be linear. Because of their rapidity and simplicity, both tests are particularly well-suited for control use in pulp mills. However, only the kappa number test has gained widespread applicability, primarily in the Kraft pulp industry. On-line optical kappa number analyzers, such as the STFI OPTI-kappa, have also been developed. The methods are based on the UV light absorption or reflectance by the sample, and the results obtained with these analyzers were generally found to be in good agreement with the conventional kappa number test.

Another approach for determining lignin in wood and pulp which has received some attention involves dissolution in a mixture of acetyl bromide and acetic acid, followed by measuring the absorbance of the solution at 280 nm. This method was later improved by incorporating a perchloric acid digestion step to ensure faster and complete dissolution of all types of samples.

Excellent agreement with the total lignin content of wood and pulps, determined as the sum of the Klason and acid-soluble lignin, was obtained using this modified procedure.

Infrared (IR) spectroscopy has also been used for estimating lignin and carbohydrates content in wood and pulp, and for studying the chemical changes in wood during pulping. The near-infrared (NIR) region is particularly suitable for lignin measurements, and several applications of this technique to the determination of lignin and cellulose have been reported. The advantage of the NIR technique is that it is considerably faster than wet chemical methods; however, it requires excessive calibrations against other established techniques for each type of wood or pulp species in order to be used reliably. When separate calibrations were used for hardwood and softwood pulps, good agreement was found between lignin determined by NIR spectroscopy and Klason lignin.

5.2.1 Functional Groups in Lignin

A comprehensive review of various methods for the determination of functional groups in lignin has recently been published. Major functional groups in lignin include phenolic hydroxyl, carbonyl, methoxyl, sulfonate, and carboxyl, all of which can have a significant effect in papermaking and on pulp properties. For example, acidic groups, including sulfonates and carboxylates, in combination with metal ions, can influence fiber swelling and various papermaking properties such as beating, drainage, and the retention of cationic chemicals. Both sulfonate and carboxylate groups can be conveniently determined by conductometric titration with sodium hydroxide after conversion of the acid groups to their hydrogen form. Brightness reversion and yellowing of paper are partly due to light-induced oxidation of phenolic structures to quinones. One of the simpler methods for determining phenolic hydroxyl groups is based on the difference in UV absorbance (250 or 300 nm) of phenolic units in neutral and alkaline solutions. The increase in absorption on increasing the pH from 6 to 12 is related to the concentration of phenolic groups in the lignin. The measurements, however, must be calibrated against lignin model compounds.

5.3 Determination of Extractives

So far, we have examined the analysis of the major components of wood and pulp: cellulose, hemicelluloses, and lignin. Extractives are considered to be a minor component, making up 2–10%, and generally less than 5%, of the weight of wood. As indicated previously,
they consist of many different classes of compounds, ranging from water-soluble materials such as tannins, gums, sugars, and starches, to those soluble in various organic solvents. The chemistry and significance of wood extractives have been described in detail, and methods for their analysis have been reviewed by Sitholé. From a pulp and paper-making point of view, the class of extractives that has received the most attention is known as wood resins. By definition, wood resins are compounds soluble in neutral, organic solvents and consist of nonpolar, lipophilic compounds, including fatty and resin acids, sterols, steryl esters, terpenes, and glycerides. A relatively high level of wood resin in pulp is undesirable because it increases the risk of pitch deposition. Certain wood species, such as birch and aspen, contain high levels of neutral wood resin compounds, mainly steryl esters, which are particularly difficult to remove during pulping and can be a serious source of deposition on paper-making equipment. In addition, during pulp bleaching with chlorine compounds, wood resin compounds such as fatty and resin acids can be chlorinated and contribute to the total organic halogen content in the effluents.

In order to assess the propensity of wood or pulp to give rise to these problems, it is important to determine both the level and the types of extractives present. Several solvents are specified in various standard methods (PAPTAC G.13 and G.20; TAPPI T204). The use of 1:2 ethanol–benzene mixture has now been practically eliminated because of the carcinogenic hazard associated with the use of benzene. Halogenated solvents, such as dichloromethane and chloroform, are also being discouraged, because of health hazards. For these reasons, the most recent versions of the PAPTAC standards specify the use of acetone for solvent extraction (PAPTAC G.13 and G.20). In general, extraction with dichloromethane gives lower amounts of extractives in both wood and pulp compared with either acetone or ethanol–benzene. On the other hand, the acetone extractives content in wood is somewhat lower than that obtained with ethanol–benzene. In the case of pulp, however, the acetone extractives content is in most cases comparable to that determined with ethanol–benzene because the compounds originally present in wood that are soluble in ethanol–benzene but not in acetone, such as polyphenols and low molecular weight carbohydrates, are largely removed during the pulping and washing processes.

A Soxhlet-type extraction apparatus is traditionally used for wood and pulp; however, more recently, a rapid extraction unit, the Soxtec System HT® (Tecator, Fisher Scientific) was evaluated and the results compared to those obtained with the traditional Soxhlet apparatus. A schematic diagram of the Soxtec extraction system is shown in Figure 4(a–c). Extraction is carried out with boiling solvent instead of condensed solvent as is the case with Soxhlet extraction. The main advantages of the Soxtec system are much shorter extraction times and recovery of the major portion of the solvent. Efficient rinsing of the sample after extraction must be carried out either by double extraction or extended rinsing. Good agreement was observed between the Soxhlet and double-rinsed Soxtec extraction with acetone on various samples of wood and pulp. The relative amounts of various components were also essentially the same by both methods for the acetone extraction of aspen wood.

More rapid and effective means of extraction than those described above are also being explored. Supercritical fluid extraction (SFE) is a relatively new technique which involves the use of a fluid above its critical temperature and pressure. Under these conditions, the fluid behaves like a gas in terms of its extracting ability. As reported by Sitholé in his review of methods for analysis of extracts in wood and pulp, there have been a limited number of publications dealing with SFE of wood and pulps, and percent recoveries are considerably different from those obtained by Soxhlet extraction. More recently, Sequeira and Taylor reported on the use of supercritical fluid carbon dioxide (SF-CO₂) and SF-CO₂ modified with 2% methanol for the extraction of a CTMP and a bleached kraft pulp. The SFE results were comparable to those obtained by Soxhlet extraction with ethyl acetate. Although SFE is faster than conventional liquid extraction, with typical average extraction time of 30 min to 2 h, compared with 1–4 h for Soxtec and 4–48 h for Soxhlet, suitable conditions must still be established before the technique can be widely used on pulp and paper samples.
Another potentially attractive extraction technique is referred to as accelerated solvent extraction (ASE™). It is based on the use of organic solvents at temperatures and pressures above their boiling point. The extraction rate is considerably increased as a result of increased solubility of extracts, improved mass transfer of the solvent, and disruption of surface equilibria which occur at high temperatures and pressures. A schematic of the ASE™ system is shown in Figure 5. The solvent is pumped into a stainless-steel extraction cell containing the sample. The cell is heated in an oven at elevated temperature (50–200 °C) and pressure (500–3000 psi). The sample extract is then purged with nitrogen into a sealed collection vial and weighed. Typical extraction times are 12–18 min per sample, and solvent consumption is also considerably reduced to 15–40 mL per sample, compared with 50–100 mL for Soxtec and 200–500 mL for Soxhlet. Recoveries of various compounds from reference materials, soil samples, and pesticides and herbicides with ASE™ were in excellent agreement to those obtained by Soxhlet extraction. The application of ASE™ to the determination of dioxins and furans in environmental samples has also been described. The technique is being evaluated by several laboratories for potential applications to wood, pulp, and other samples from the pulp and paper industry.

5.3.1 Detailed Analysis of Extractives

Analysis of extractives in wood and pulp involves preliminary solvent extraction of the sample, followed by fractionation and chromatographic analysis of the extracts. Capillary GC is commonly used for these analyses. A comprehensive scheme for the separation and analysis of extractives in pulp was proposed by Ekman and Holmbom (Figure 6). Lipophilic and polar extractives were successively extracted with dichloromethane and acetone–water (9:1). A portion of the lipophilic fraction was hydrolyzed to determine total (free and esterified) extractives. Both hydrolyzed and unhydrolyzed fractions were then derivatized by methylation and silylation. Analysis was carried out by capillary GC combined with MS. Figure 7 shows a TIC of lipophilic extractives in a pulp sample. Identification of the various compounds is shown in Table 4.

*a* Compounds were detected by MS of the Me esters/TMSi ethers (abbreviations in parentheses). Several compounds (e.g. peaks 46–66) listed in this table are not present in Figure 7, but were detected on other types of samples or using different conditions.

*b* Me ester/Me ether internal standard heptadecanoic acid.

Another scheme involves the use of ion-exchange chromatography to fractionate acetone extracts into weak acids, strong acids and neutrals. A weak ion-exchange resin bed was used for this purpose, and elution was carried out successively with diethyl ether, diethyl ether saturated with CO$_2$, and formic acid to recover neutrals (hydrocarbons, alcohols, esters, etc.), weak acids (fatty and resin acids), and strong acids, respectively. Samples were derivatized with diazomethane and analyzed with capillary GC. A novel feature of this approach is the use of short (2 m) fused-silica capillary columns to separate the main classes of extractives into fatty acids, fatty alcohols, sterols and triterpene alcohols, waxes, diglycerides, steryl esters, and triglycerides. A typical chromatogram of a standard mixture is shown in Figure 8, and the peaks are identified in Table 5. This technique can be combined with fast temperature programming to elute the compounds of interest in about 15 min.

Other approaches have also been developed for the separation of extractives into individual classes. The use of reversed-phase HPLC with a mass detector has been reported by Suckling et al. for the analysis of fatty acids, resin acids and triglycerides in softwood extractives. More recently, thin-layer chromatography (TLC) was used to separate acids and neutral compounds, including sterols, triglycerides, and steryl esters, in extracts from bleached CTMP and kraft pulps. Extracts were applied to silica-coated plates and neutrals were eluted with heptane–acetone–ammonia and fatty and resin acids with dichloromethane–methanol–ammonia. The eluted compounds were quantified using a scanning UV detector.

Analysis of individual fatty and resin acids is best carried out on medium-length (20m) fused-silica capillary columns such as SE-30 or Carbowax columns, as reported by Dorris et al. In this work, the use of equivalent chain length for expressing the retention of a compound, and also the effects of several variables, including temperature, splitting ratio, and method of injection, on the precision and accuracy of the analysis were critically examined. Fatty and resin acids must be converted into volatile derivatives prior to GC analysis. Derivatization procedures were recently described in a review by Sitholé on methods of extractives analysis. They include conventional methylation with diazomethane, trimethylsilylation, ethylation, and pentfluorobenzyla- tion, and also rapid in situ methylation with trimethylammonium hydroxide. Because of its speed and simplicity, in situ methylation is often used for many applications.

A rapid spectrophotometric method for determining total fatty and resin acids in pulp and paper samples was reported by Sitholé. After solvent extraction, the resin and fatty acids (RFA) were complexed with cupric ions, extracted, and their concentrations determined colorimetrically. The results were in good agreement with those of the GC method.

5.4 Determination of Inorganics

The next class of minor components of wood and pulp are the inorganics, which together generally make up less than 1% of the weight of wood. Potassium, calcium, and magnesium account for 70–80% of the total ash content. In spite of their presence at such low levels, inorganics can have a significant negative impact on a mill operation and on pulp properties. The content and composition of inorganics in wood and pulp must be determined for a variety of reasons: to conduct mass balance studies in order to establish the distribution of particular elements in the system to assess the impact of certain elements, such as calcium, on scaling and pitch deposition to determine the effect of various inorganic constituents in kraft liquors on the pulping and recovery processes or to carry out fundamental studies of the distribution of elements at the morphological level to list only a few. The presence in pulp of certain transition metals, particularly iron, manganese, and copper, can have several deleterious effects on pulp properties and on the consumption of bleaching chemicals. In particular, metal ions are often responsible for brightness reversion and a decrease in pulp brightness through the formation of colored complexes with lignin. They can also induce, through catalytic and free radical reactions, the degradation of cellulose during oxygen and ozone bleaching. In addition, metal ions cause the decomposition of hydrogen peroxide used in pulp bleaching. These problems can be considerably aggravated if high levels of bark are present in the wood furnish, owing to the much higher level of metals in bark. The type and levels of metals must therefore be determined to control such problems.

In finished paper and board products, the determination of inorganics provides information on the level and type of fillers, coatings, and other additives, such as clay, calcium carbonate, titanium dioxide, alum, and talc.

The total level of inorganics is generally determined by simply destroying the organic matter in a furnace at
a temperature of 525–575 °C (PAPTAC G.10; TAPPI T211) or 900 °C (PAPTAC G.11; TAPPI T413). The portion of ash insoluble in hydrochloric acid is usually taken as an approximate measure of the silicates content, and referred to as acid-insoluble ash (PAPTAC G.33; TAPPI T244).

Determination of specific elements in wood and pulp requires either dry ashing or wet digestion of the sample prior to analysis. Dry ashing is generally performed at 525–575 °C. The use of higher temperatures is not recommended because it can lead to substantial losses of metals, particularly sodium, calcium, copper, and iron. This problem can be circumvented by the use of wetashing techniques. The latter involve treating a wood or pulp sample with oxidative chemicals to destroy the organic matter and liberate the free metals in solution. Various mixtures can be used for digestion, including sulfuric acid and hydrogen peroxide, or more conveniently perchloric and nitric acid (PAPTAC G.30). However, the use of perchloric acid is especially hazardous because of the risk of formation of explosive perchlorate compounds. Special procedures and precautions are required for perchloric acid digestions. Microwave digestion in pressurized vessels has become increasingly popular, partly because of safety considerations, since no perchloric acid is used, and because it is considerably faster than conventional wet digestion methods. It has recently been applied to the digestion, using only nitric acid, of a wide range of wood sawdust and wood flour samples. It has also been used for digestion of tree foliage and several standard materials, including pine needles, using sequential addition of nitric acid, hydrogen peroxide, and hydrochloric acid.

Following dry ashing or wet digestion, analysis of elements is generally carried out by atomic absorption spectrometry (AAS) or by inductively coupled plasma atomic emission spectrometry (ICP-AES). Although flame AAS is commonly used, graphite furnace (electrothermal) atomization has also been applied to the determination of trace metals in pulp. ICP-AES is finding increasing use in pulp and paper applications because of its ability to determine sequentially or simultaneously a wide range of elements, including aluminum, silicon, phosphorus, and sulfur.

X-ray methods can also be applied to the determination of elements in pulp and paper samples. Kocman and Bruno used X-ray fluorescence (XRF) spectrometry for determining a wide range of fillers, including clay, titanium dioxide, calcium carbonate, and talc, in fine papers, newsprint, and recycled stock. Paper samples were first pulverized in a laboratory blender, pressed into a pellet using a hydraulic press, and then analyzed with a wavelength-dispersive X-ray instrument. Keitaanniemi and Virkola also used XRF spectrometry for the determination of inorganic components in solid samples, including wood, bark, pulp, furnace smelt, dust, lime, lime mud, grits, and dregs. The advantage of this technique is that the sample can be analyzed directly without prior ashing or digestion. However, the XRF analysis is subject to matrix effects and requires careful calibration to yield reliable results.

Another powerful nondestructive method for elemental analysis is neutron activation analysis (NAA). Samples are irradiated with a neutron source and, based on the energy and level of emitted γ-rays, the type and concentration of a particular element can be determined. This technique was applied to the measurements of elements in black spruce wood, and the results were generally in good agreement with those obtained by ICPAES.

Energy-dispersive spectroscopy (EDS) combined with scanning electron microscopy (SEM) is an effective and rapid tool for mapping the distribution of elements in a sample. Ormerod et al. described the application of this technique to the determination of fillers, coating additives, and contaminants throughout a paper sheet. Hillis and de Silva applied a similar technique to the analysis of deposits in morphological regions of wood. This approach, however, is generally used only for qualitative or semiquantitative analysis.

Elemental distributions at the morphological level can also be obtained through the use of secondary ion mass spectrometry (SIMS). Bailey and Reeve described the application of this technique for determining the spatial distribution of metals in several morphological features of black spruce wood.

6 ANALYSIS OF PROCESS LIQUIDS

For the purpose of this discussion, process liquids have been divided into two parts: process liquors which include pulping, bleaching, and spent liquors, and process waters and effluents.

6.1 Analysis of Process Liquors

Routine analyses are performed on pulping liquors to determine the concentration of active chemicals, to adjust digester charge, and to follow the progress of a cook. In the latter application, samples can be withdrawn at various stages during pulping and analyzed to determine the consumption of various chemicals. The major types of pulping liquors are those used in the sulfite and kraft processes.

6.1.1 Sulfite Liquors

In the sulfite process, pulping liquors are produced by absorbing sulfur dioxide gas in a base, such as calcium,
calculation of both true free and combined SO2 depends on the ratio of SO2 to alkali. Table 6 presents the approximate composition of the four major sulfite cooking liquors. Sulfite cooking liquors cover a wide range of compositions depending on the pH of the liquor and the ratio of SO2 to alkali. Table 6 shows the approximate composition of the four major sulfite processes over a starting pH ranging from 1–2 for the acid process to 10–13 for the alkaline process. As indicated in Table 6 and discussed in detail by Ingruber, the calculation of both true free and combined SO2 depends on the pH level, and may differ from free and combined SO2 determined by the standard titration method.

* M = monovalent cation (Na+, NH4+, 1/2Ca2+, 1/2Mg2+).

Determination of the various forms of SO2 is important because of their significant impact on the pulping rate and pulp properties. The level of combined SO2 affects chip penetration, pulping rate, and strength properties. Increasing the level of combined SO2 results in increased brightness and tensile strength of the pulp. On the other hand, too high a level of combined SO2 can result in a decreased pulping rate. Free SO2 affects mainly the pulping rate, and total SO2 has an impact on several factors, including chip penetration, rejects level, brightness, and bleach demand. A particularly important parameter in sulfite cooking is pH, which influences pulp yield, pulping rate, brightness, and strength properties. It is especially critical in bisulfite pulping where a small variation in pH can have a significant effect on these factors.

6.1.2 Kraft Liquors

In the kraft process, pulping and spent liquors are continuously generated in a cyclic liquor system (Figure 9). The pulping or cooking liquor, also known as white liquor, is combined with the wood in a digester. After cooking, the spent liquor, referred to as black liquor, is removed during washing, concentrated in several stages of evaporation, and then burned in a recovery furnace. The resulting smelt is dissolved in water to produce the so-called green liquor. The latter is converted back to white liquor in a causticizer. This section examines the more common types of analyses conducted on kraft white, green, and black liquors.

The active components in a kraft white liquor are sodium hydroxide and sodium sulfide. The main parameters that are determined routinely in white liquors are the effective alkali (EA) charge, the initial alkali concentration, and the sulfidity, all of which have a profound effect on the pulping process and on pulp quality. The EA is defined as NaOH + 1/2Na2S, expressed as Na2O, and sulfidity as Na2S/(NaOH + Na2S), expressed as Na2O.

Increasing the EA reduces pulp yield, but an excess EA at the end of the cook also results in improved pulp brightness. The alkali concentration charged at the start of the cook affects mainly chip penetration and the rate of delignification. Both the rate of delignification and pulp strength properties are improved with increased sulfidity.

The traditional method for analyzing white liquors is known as the ABC titration, which involves a three-step titration with hydrochloric acid, with successive addition of barium chloride and formaldehyde. The end-points are used to calculate the various alkali charges, and also the concentration of sodium carbonate. The latter is present as a result of incomplete conversion of sodium carbonate to sodium hydroxide in the causticizing step of the kraft recovery process. In addition to carbonate,
several other nonprocess components are present in white liquors and are referred to collectively as ‘dead load’. They include a range of inorganic sodium salts, such as sodium sulfate, thiosulfate and chloride, and metal ions including potassium, calcium, magnesium and iron, and silicates. These originate from the wood, chemicals added in the recovery process, or from incomplete conversion of compounds in the recovery process. A high dead load is undesirable because it reduces the efficiency of lignin removal, and can give rise to various operating problems such as corrosion and deposition on process equipment.

The ABC titration can also be used to analyze green liquors for sulfide and carbonate. However, in addition to sodium salts, green liquors also contain a number of impurities, consisting mainly of metallic compounds, such as silicates, aluminates, and carbon, which must be largely removed by sedimentation in a clarifier before the causticizing process. Therefore, total solids and inorganics content must be known because they can affect the efficiency of the clarification process. The ratio of lime to calcium carbonate must also be determined because it affects the causticizing efficiency. A ratio close to 1 is desirable for optimum efficiency.

Black liquors are also analyzed for a variety of parameters. Residual alkali provides an indication of alkali consumption during the cook and is most accurately determined by potentiometric autotitration to a weak inflection point. An excess alkali at the end of the cook is usually desirable because it ensures maximum solubilization of the resin, which, in turn, reduces the risk of pitch deposition. Analyses of sodium and dissolved solids content in black liquors are also performed routinely as a measure of washing efficiency and to determine the amount of makeup chemicals. A rapid method for determining kraft black liquor solids was proposed by McDonald. Other black liquor tests include viscosity, boiling point, specific heat, and soaps and inorganics content. All of these parameters affect the efficiency of evaporation and subsequent burning in the recovery boiler.

In addition to several standard or official methods for the analysis of kraft liquors (PAPTAC J.12, J.15; TAPPI T624 and T625), a variety of instrumental techniques have

Figure 9 Diagram showing cyclic nature of the kraft recovery process. (Reproduced by permission of PAPTAC from T.M. Grace, B. Leopold, E.W. Malcolm, M.J. Kocurek, Pulp and Paper Manufacture, 3rd edition, Joint Textbook Committee of the Paper Industry, Montreal, Vol. 5, 1989.)
also been devised for determining the active chemicals and dead-load components in these liquors. Potentiometric titration with mercuric chloride using a sulfide ion-selective electrode has been widely used for the analysis of various sulfur species. Pulse polarography was also shown to be an effective technique for determining sulfide, sulfite, and thiosulfate. Ion chromatography (IC) is a highly versatile and proven technique for measuring a wide range of inorganic and organic anions in kraft and other types of pulp and paper liquors. Standard methods for the analysis of pulping liquors, based on IC, have also been introduced (PAPTAC J.20; TAPPI T699).

One of the major drawbacks of the technique is that high levels of dilution are required, which can result in measurement errors, particularly for sulfide, sulfite, and thiosulfate owing to shifts in equilibrium concentration between sulfur species during sample dilution. Many of these problems can be largely circumvented, however, by analyzing the samples immediately after dilution.

A typical ion chromatogram of a kraft black liquor is shown in Figure 10. More recently, CE was used for the determination of various sulfur species, and also several other anions, including hydroxide, chloride, oxalate, and carbonate, in kraft pulping liquors. Examples of electropherograms of white and black liquors and of a standard solution are shown in Figure 11. The main advantages of the CE approach compared with IC are its speed, its ability to determine simultaneously a wide number of ions in a sample, and the use of inexpensive capillary columns.

Considerable progress has also been achieved in the area of on-line measurement of kraft liquors. Alkali and sulfide consumptions during kraft cooking were measured using a conductivity detector and on-line IC. Another approach involves the use of attenuated total reflectance IR spectroscopy. EA, carbonate, sulfate, and thiosulfate could be determined by this technique in laboratory experiments on kraft liquors. It has also been applied to on-line measurements of EA and carbonate in these liquors.

In a modified version of kraft pulping, referred to as polysulfide pulping, significant amounts of sodium polysulfide (Na₂Sₓ, where x = 2 – 5) are generated in the white liquor, typically by oxidation of sodium sulfide present in the liquor. The use of polysulfide in kraft pulping is known to produce an increase in pulp yield. This beneficial effect is attributed to the oxidation by polysulfide of the reducing end groups of polysaccharides, thereby stabilizing them against the so-called peeling or degradation reaction.
Figure 12 Gas chromatogram obtained in the determination of sulfur, from the decomposition of polysulfide, by the TPP method.\textsuperscript{(104)} Peaks: 1 = internal standard; 2 = TPP; 3 = triphenylphosphine oxide (TPPO); 4 = TPPS. TPPO is formed by the action of TPP with dissolved oxygen in the sample. (Reprinted from L.G. Borchardt, D.B. Easty, \textit{J. Chromatogr.}, \textbf{299}, 471–476 (1984), Copyright 1984, with permission from Elsevier Science.)

which takes place during conventional kraft pulping. Several methods have been devised for measuring the concentration of polysulfide in these liquors. The potentiometric method with mercuric chloride and a sulfide ion-selective electrode described by Papp\textsuperscript{(89)} can also be used for determining polysulfide. The polysulfide is determined by measuring thiosulfate before and after addition of sulfite to the sample. A spectrophotometric method based on the measurement of absorbance at 285 nm has also been reported by Teder.\textsuperscript{(103)} Another method involves reduction of polysulfide with sodium amalgam and measuring the sulfide content before and after the reduction step by potentiometric titration with mercuric chloride (TAPPI T694). More recently, a direct method was reported involving decomposition of polysulfide to elemental sulfur. The sulfur was then derivatized with triphenylphosphine (TPP), and the resulting triphenylphosphine sulfide (TPPS) was determined by GC with flame ionization detection (FID).\textsuperscript{(104)} Figure 12 shows a typical gas chromatogram obtained by this method. Good agreement was reported with the sodium amalgam method on commercial polysulfide liquors. A modified approach to this method involves gravimetric determination of elemental sulfur precipitated by acidification of polysulfide solutions.\textsuperscript{(105)} The same authors recently reported using a new end-point in the ABC titration of polysulfide liquors to obtain a measure of polysulfide along with other sulfoxy anions.\textsuperscript{(106)}

6.1.3 Bleaching Liquors

Bleaching liquors represent another type of process liquors that require frequent analysis. The subject of pulp bleaching is covered in detail in several excellent textbooks and monographs.\textsuperscript{(107–109)} The major bleaching agents used in the pulp and paper industry are listed in Table 7. Kraft bleaching liquors consist mainly of chlorine dioxide, sodium hydroxide, sodium hypochlorite, and hydrogen peroxide. The use of elemental chlorine in pulp bleaching has decreased dramatically since its role in the formation of chlorinated dioxins and furans was recognized. Oxygen and ozone are used to a limited extent at the moment, mainly in totally chlorine-free (TCF) bleaching installations. Mechanical pulp are commonly bleached with hydrogen peroxide or sodium hydrosulfite. Several standard methods, based primarily on titrimetry, are available for analysis of generator and spent bleaching liquors (PAPTAC J.2, J.14, J.16, J.17 and J.22; TAPPI T611, T613 and T622). A more recent TAPPI method (TAPPI T700) is based on the use of IC for determining the major chlorine and oxychlorine species. Several problems with the use of IC for the determination of these species, including incomplete recovery of chlorine dioxide during analysis and interferences with organic ions, were recently identified and resolved.\textsuperscript{(110)} Based on analytical conditions developed in this work, excellent recovery of spiked bleaching effluent samples was obtained. Figure 13(a) and (b) shows typical ion chromatograms of a sample of a chlorine dioxide effluent. The use of both conductivity and UV modes of detection allowed better separation of certain ions to be achieved. For example, the response of chlorite with a UV detector was significantly higher than that of organic acids, providing a more reliable means of quantifying chlorite in the presence of high concentrations of formate.

6.2 Analysis of Process Waters and Effluents

Mill effluents consist of process waters and filtrates that are discharged from various unit operations of the pulp and paper-making process. Effluents are characterized for a wide range of parameters and for various purposes, including assessing the level of priority pollutants, conducting mass balance studies to establish the distribution of various components in a system, and determining the effect of various operating conditions, such as washing efficiency, white water closure, and water treatment processes on the removal or buildup of various components in the system. With the trend toward increased system closure in mills to limit the discharge of effluents into receiving waters, the levels of dissolved, colloidal, and suspended material could also increase significantly. This could, in turn, impact on paper machine runnability and product quality.

Some of the common tests conducted on process waters and effluents are listed in Table 8. Most of these tests are based on well-established industry methods and standards (PAPTAC H.4; TAPPI T620).\(^{111}\) Several of the instrumental techniques for determining some of these parameters, including IC for anion analysis and AAS or ICPAES for metals, have already been described in previous sections. Other tests for determining basic properties such as solids, turbidity, color, and pH, are straightforward and require no further explanation. Subsequent discussion will therefore be limited to the more elaborate tests and to those based on the use of new analytical schemes and instrumentation.

The BOD, COD, and TOC tests provide a measure of the organic matter in the sample. The BOD is a measure of the amount of oxygen consumed by decomposition of organic matter by microorganisms added to the sample. In the standard BOD test (PAPTAC H.2), the oxygen content in the sample is measured before and after incubation with microorganisms over a 5-day period. Several sources of error have been identified to account for the high variability of the test results,\(^{112–114}\) including water quality, viability of the seed source, use of nitrification inhibitor, and presence of toxicants in the sample. However, the BOD test continues to be widely used as an indicator of the level of organic pollutants in wastewaters.

One of the major drawbacks of the standard BOD test is that it takes 5 days to complete, which makes it impractical for process control. A number of faster alternative approaches have been proposed. One of them is simply based on correlating 24-h BOD results with the 5-day conventional test.\(^{115}\) A good correlation was obtained between the two tests with untreated and

The actual table from the text includes additional tests and a specific format. For a complete representation, please refer to the original text.
biologically treated paper mill effluent. Another report showed good correlation between BOD 5-day test results on spent sulfite liquor and carbohydrate content.\(^{(116)}\)

Instrumental techniques, based on respirometry, for measuring oxygen uptake on a continuous basis, have received considerable attention. Several types of commercial instruments are available, including manometric, volumetric, electrolytic, and direct-input respirators, depending on the method used for determining oxygen consumption.\(^{(117)}\) In all cases, carbon dioxide produced during oxygen uptake is removed from the air space. More recently, the use of microbial oxygen sensors,\(^{(118,119)}\) the acceleration of respiration rate is measured by the change in electric current. An optical fiber sensor for BOD measurement has also been reported.\(^{(120)}\) In this case, the sensing membrane contains an oxygen-sensitive fluorescent material. Typical response times are 5–10 min. Another advantage of optical type sensors is that oxygen is not consumed in the process. BOD results with both amperometric and optical sensors were found to correlate well with the 5-day BOD test on various municipal wastewaters and effluents. Although BOD sensors have the potential for considerably reducing measurement time, they have not yet been widely adopted for commercial pulp and paper mill applications.

The COD test is a measure of oxidizable material in the sample under specified conditions. In one of the standard tests (PAPTAC H.3), denoted the “open reflux” method, the sample is refluxed with potassium dichromate under strongly acidic conditions. Excess dichromate is determined at the end of the reflux period by titration with ferrous ammonium sulfate. In general, COD test results are much higher than those obtained with the BOD test, because the conditions of oxidation are much more severe. The determination of COD can also be carried out more rapidly and conveniently by a “closed reflux” colorimetric method.\(^{(121)}\) In one version of this approach, the sample is placed in a small digestion tube and heated in an oven at 150 °C for 2 h using a mixture of chromic and sulfuric acid. The time can be reduced further by using microwave digestion.\(^{(122)}\) After cooling, the absorbance is measured at 600 nm. Absorbance at that wavelength is related to the increase in Cr\(^{3+}\) resulting from the oxidation of chromium from the hexavalent (Cr\(_2\)O\(_7^{2-}\)) to the trivalent state. Complete systems for the closed reflux method are available commercially (e.g. from Hach). The method has been shown to give comparable results to the standard titrimetric procedure.

In the TOC test, all the organic carbon originating from both oxidizable and nonoxidizable matter is determined in the sample. Organic carbon is converted into CO\(_2\) using either UV radiation, chemical oxidants, or high temperature, and the liberated CO\(_2\) is then measured by IR spectroscopy or coulometric titration.\(^{(123)}\)

Another group parameter for evaluating the level of halogenated organic material is AOX. This test measures the level of halogens, primarily present as chlorine, bound with organic compounds. In mills using chlorine compounds for bleaching, AOX levels must be below certain levels, as determined by environmental regulations. In standard AOX tests\(^{(124)}\) (PAPTAC H.6; SCAN W9), the sample is adsorbed on granular activated carbon (GAC). Inorganic halides are removed by washing. The adsorption can be carried out in GAC-packed columns (column method) or by shaking the sample with GAC for a specified time (shaker method), as illustrated in Figure 14(a) and (b).\(^{(125)}\) The GAC with adsorbed organic material is pyrolyzed in a combustion furnace and the organic halogens are determined by microcoulometric titration. Several potential sources of variability in the AOX test, including discrepancies between shaker and column results, and sample storage conditions, as well as measures to avoid these problems, have been reported by Sullivan and Douek.\(^{(126)}\)

![Figure 14](image-url) Schematic diagram illustrating the adsorption of samples on activated carbon for AOX determinations, using (a) the column or (b) the shaker method.\(^{(125)}\) (Reproduced by permission of Southam from S.M. Odendahl, K.M. Weishar, D.W. Reeve, *Pulp Paper Can.*, 91(4), T136–T140 (1990).)
In addition to the various tests described so far, detailed analyses of the dissolved and colloidal material released into process waters and effluents can provide valuable information on the nature and level of specific components present in the system. For example, certain lipophilic extractives, such as fatty and resin acids, sterols, and glycerides, can produce an increase in effluent toxicity, give rise to deposition problems on process equipment, and affect paper quality.

Several schemes, using a wide range of analytical techniques, for separating this material into classes or individual components have been devised. A simple scheme for separating both the lipophilic and polar extractives in a water sample from groundwood pulping of spruce was devised by Ekman and Holmbom.\(^{60}\) The scheme is similar to that shown in Figure 6 for pulp samples, except that in the initial step the lipophilic material was separated from polar compounds by extraction with diethyl ether. A portion of the ether extract was saponified by alkaline hydrolysis to liberate the free fatty acids, alcohols, and sterols bound as esters in the original sample. Both the extracts and residue after extraction were then derivatized and analyzed by GC or GC/MS.

The use of methyl tert-butyl ether (MTBE) for extracting RFA in pulp mill effluents has also been reported.\(^{127}\) Extraction of the sample at pH 9 with this solvent appears to overcome several problems, such as emulsion formation and lignin precipitation, which occur with other solvent extraction techniques. Orsa and Holmbom\(^{128}\) have also demonstrated the use of MTBE for extraction of free and esterified wood resin, and also phenolic low molecular weight components, such as lignans, from TMP process waters, followed by GC. They determined the dissolved lignin from the UV absorption of the extracted water sample at 280 nm. The ability to distinguish between low molecular weight lignans and high molecular weight lignin is important, because lignans do not consume cationic polymers used in paper-making, whereas lignin does. On the other hand, lignans may reduce paper brightness.

Another convenient method for isolating lipophilic extractives from pulp mill process waters involves the use of solid-phase extraction. Backa et al.\(^{129}\) have shown that fatty and resin acids and triterpenoic extractives were efficiently retained on a C\(_{18}\) hydrocarbon-substituted solid-phase disposable column. Undesirable material retained on the column was removed with an aqueous alkali solution containing methanol. The extractives were then eluted by sequential addition of ethanol and dichloromethane and analyzed by GC. The method was primarily developed for highly contaminated samples such as black liquors, but could also be applied to other types of process liquids. A similar technique, using silica Sep-Paks or C\(_{18}\) extraction cartridges, was applied by Sweeney\(^{130}\) for the separation of several organic fractions in various types of pulp and paper samples, including mill process streams, and for black liquor cleanup. Compared with conventional solvent extraction techniques, solid-phase extraction methods are relatively simpler and faster, and require much less sample and solvent.

The environmental impact of mill effluents is also dependent on the molecular weight distribution of the organic material in a sample. For example, some of the low molecular weight organic halogen compounds produced during pulp bleaching accumulate in aquatic organisms. On the other hand, high molecular weight material, which constitutes the major portion of organic halogen compounds, is considered to be biologically inert. A large body of work has been published by several workers on the determination of molecular weight distribution and characterization of various fractions in bleached kraft mill effluents. Jokela and Salkinoja-Salonen\(^{131}\) described the use of aqueous and nonaqueous SEC and ultrafiltration to determine the molecular weight distribution of pulp bleaching organic halogen compounds. Their work showed that both dilution of sample and solvent type can significantly affect the apparent molecular weight distribution, due to micelle formation in concentrated samples, and intermolecular association in various solvents. Detailed structural analysis of the high molecular weight fractions of both alkaline and acid kraft mill spent bleach liquors was reported by Lindström and Østerberg.\(^{132,133}\) The liquors were subjected to several steps of ultrafiltration and fractions were characterized by a variety of techniques including infra-red and \(^1\)H and \(^{13}\)C nuclear magnetic resonance (NMR) spectroscopy for structural identification. GC, MS, and microwave multiple plasma emission spectroscopy for elemental analysis were used on low molecular weight fractions and on degradation products. Similar detailed studies were conducted by Dahlman et al.\(^{134,135}\) on the high molecular weight fractions from elemental chlorine-free (ECF) and TCF bleaching effluents. Determination of dissolved carbohydrates from unbleached and bleached TMP pulp has also recently received considerable attention, because of their potential impact on the paper-making process.\(^{136}\) In particular, polygalacturonic acids, released during peroxide bleaching of mechanical pulp, were shown to have a detrimental effect by consuming significant amounts of cationic retention aids through complex formation.\(^{137,138}\)

7 ANALYSIS OF PAPER

As indicated at the beginning of this article, a large proportion of chemical tests conducted in the pulp and
The starch, addition of iodine to the filtrate, and detection (PAPTAC G.23; TAPPI T419) are based on extraction of Standard methods for determining starch in paper as adhesive in paper and board converting processes. in surface sizing, as binder in coating formulations, and starch. This was followed by mass spectral analysis of the paper had been decomposed and its products vented, subsequent pyrolysis was carried at higher temperatures. These results were in good agreement with the chromatographic A method for determining free and bound AKD in paper industry are performed on wood pulp, process liquors and effluents. There are relatively few quantitative chemical analyses that are routinely performed on paper products. Some of the methods described for wood pulp, for determination of basic parameters such as ash, silicates, metals, and extractives content, are also generally applicable to paper products. Most of the tests performed on paper are designed at determining various additives used in paper-making for a wide range of applications. A list of the major types of additives, used in paper-making, is given in Table 9. For control purposes, simple qualitative analyses, involving the use of spot tests with specific dyes, chemical reactions with selected reagents, solubility tests, observation of physical characteristics, and microscopic examination, are used to establish the presence or absence of a particular additive. A comprehensive description of some of the traditional detection and control tests applied to paper products is given by Browning, and in the various industry standard methods. Only the more recent developments in the analysis of paper additives will be covered in the remaining part of this section.

One of the most widely used paper-making additives is starch. It is used for improving the dry strength of paper, in surface sizing, as binder in coating formulations, and as adhesive in paper and board converting processes. Standard methods for determining starch in paper (PAPTAC G.23; TAPPI T419) are based on extraction of the starch, addition of iodine to the filtrate, and detection of the blue starch–iodine complex. For quantitative measurements, this is done by measuring the absorbance at about 580 nm. However, the iodine test is not considered reliable because it is dependent on the ratio of amylose to amylopectin, the two polymeric forms present in starch, and on the molecular weight of the starch, and because both of these factors could change during processing and sample preparation. Another approach which circumvents these problems has recently been developed. It involves hydrolysis of the starch to glucose using a combination of two types of enzymes specific to starch, a-amylase and glucoamylase. After hydrolysis, the glucose is determined by HPLC or spectrophotometrically. This enzymatic hydrolysis method has now been adopted by several laboratories. However, since some types of modified starches, such as cationic starches, will produce a lower yield of glucose after hydrolysis, it is always preferable to compare the results with a calibration curve obtained with the same type of starch as that used in the paper sample.

Pyrolysis/gas chromatography (py/GC) has been widely applied to the determination of various paper and board additives, including wet-strength resins, such as polyamide–epichlorohydrin, neutral sizing agents such as AKD and ASA, surface sizing agents, including SMA and styrene acrylate, and a variety of other polymers in paper. The advantages of this technique are its speed and simplicity, since practically no sample preparation is required. However, pyrograms can be very complex, particularly if several polymers are present in the sample. In order to remove the interference from the paper itself, a low-temperature prepyrolysis technique was described by Crockett et al. After the paper had been decomposed and its products vented, subsequent pyrolysis was carried at higher temperatures. This was followed by mass spectral analysis of the pyrolysis products to identify various polymers present in the sample.

A method for determining free and bound AKD in paper samples was also reported by Sitholé et al. It involves extraction of the paper with chloroform before and after digestion with hydrochloric acid or sodium carbonate, followed by GC. For better results, free AKD was converted by hydrolysis to stearone prior to GC analysis. A simpler and faster method for determining AKD was also reported by Nyarku and Sitholé. The method is based on potentiometric titration and the results were in good agreement with the chromatographic method.

Gel permeation chromatography (GPC) coupled with IR spectroscopy has also been applied to the identification of PVA and styrene–butadiene-based latex binders in paper coatings. The paper samples were first extracted with acetone, and THF was used in the GPC system as

the mobile phase. A nebulizer was used to vaporize the effluent from the GPC column and deposit it on a collection disk on a rotating stage. After evaporation of the solvent, the nonvolatile extractables on the collection disk were analyzed by reflectance IR spectroscopy. From a knowledge of the disk rotation speed and the distance between a spot on the disk and the start point, the spot could be correlated to a time-fraction on the GPC chromatogram. The GPC/IR approach could potentially be applied to other extractable polymers. One of its main advantages is that it allows various polymers in paper extracts to be separated with little or no interference from other components. It is also superior to sequential solvent extraction, which is more time-consuming and not entirely selective.

Surface spectroscopic techniques have also been applied to the characterization of paper additives. Electron spectroscopy for chemical analysis (ESCA) was used to identify pigments (clay and calcium carbonate) and latex binders on coated papers. This technique, together with SIMS, was also used to characterize internal and surface sizing agents in paper. The difference between the two techniques is that ESCA can only detect the presence of such additives, but provides little structural information. On the other hand, with SIMS, the chemical structure of the additive can be identified. Both techniques, however, can provide information on the spatial distribution of sizing agents on the paper surface.

8 ANALYSIS OF DEPOSITS AND CONTAMINANTS

In pulp and paper production, a large number of chemical components are released, in soluble, colloidal or insoluble form, into process waters. Some of them are transferred from pulp fibers into the surrounding liquid phase, whereas others are added to the system for specific purposes. Major components present in the paper-making process include carbohydrates, lignin, wood resin, soaps, defoamers, sizing agents, and inorganic materials such as clay, talc, and calcium carbonate. Under certain conditions of pH, temperature, and degree of mixing, or at certain concentration levels, some of these components can precipitate or agglomerate, resulting, in some cases, in major operational and quality-related problems. Common symptoms include deposition on paper-machine equipment, forming fabrics, and press felts. The consequences of these so-called pitch deposits range from premature replacement of fabrics and felts, to sheet breaks and holes in the paper. Small particles can also be carried through to the finished product, causing dirt spots or streaks which can downgrade the quality of the paper and create further problems during printing and converting processes. These problems can be considerably aggravated when recycled fibers are used in the papermaking furnish. Contaminants from wastepaper, commonly referred to as stickies, originate from a variety of sources, including pressure-sensitive adhesives, hot melts, coating binders, ink, wood resin, rosin size, and wet-strength resin. In addition, deinking chemicals used in the flotation process can contribute to the deposits.

Analysis of a particular deposit on process equipment or contaminant in paper is often the first step toward finding an appropriate solution to the problem. By tracing the source of deposition or contamination to specific components in the system, more effective control measures can be devised. Most deposits consist of a complex mixture of compounds present in varying proportions, and consequently elaborate analytical schemes are required for their identification. A review of the various analytical procedures and techniques for analysis of pitch deposits was published recently by Sithole.

A general scheme for the analysis of paper machine deposits has been described by Sjöström and Holmbom. It involves the separation and fractionation of various components in a deposit, followed by characterization of each fraction using various techniques. This general scheme was applied by Sjöström et al. to several other deposits and spots from a newsprint mill using deinked pulp. As outlined in Figure 15, samples were first examined by microscopy to determine a number of

![Figure 15](Image)
features such as homogeneity, color, stickiness, and presence of fibers and particles. They were then dissolved in THF and the soluble material was further fractionated by SEC into polymers, oligomers, and monomers. Details of the SEC technique were described by the same authors in another publication.\textsuperscript{156} IR analysis was performed on each SEC fraction for general identification of major functional groups. py/GC was used for identifying polymers, such as styrene–butadiene copolymer, in the high molecular weight fraction. The second fraction consisting mainly of triglycerides and sterol esters was hydrolyzed to liberate free fatty and resin acids which could then be determined by GC and GC/MS. The same techniques were used to characterize the third fraction consisting mainly of fatty and resin acids and other low molecular weight components such as plasticizers used in adhesive formulations. TLC was also used on the second and third fractions to establish the polarity and confirm the identity of the various components. The use of TLC for identifying pitch and paper additives, such as retention aids and defoamers, in mill deposits was reported previously.\textsuperscript{157}

A method specifically designed for analysis of deposits from newsprint mills using recycled fiber was proposed by Guo and Douek.\textsuperscript{151} As illustrated in Figure 16, it consists of sequential solvent extraction of a deposit with ethanol and chloroform. The ethanol extracts were redissolved in hexane and the hexane-soluble fraction was fractionated using solid-phase extraction as described by Sweeney.\textsuperscript{130} Several techniques, including Fourier transform infrared (FTIR) spectrometry, GC, NMR, and thermogravimetric analysis (TGA), were used to characterize both soluble and insoluble fractions. Metal soaps were also determined on a separate fraction of the deposit as described by Sitholé et al.\textsuperscript{158} The advantage of this scheme is that it simplifies the identification of the major classes of compounds, including wood resins, hydrocarbon oil, and extractable and nonextractable polymeric material, by separating them into individual fractions on the basis of differences in solubilities in different solvents. However, certain types of compounds, particularly polymers with wide molecular weight distributions, could be present in more than one fraction. One particular fraction obtained from the ethanol extract of a paper-machine dryer fabric deposit was readily identified as PVA by comparing its FTIR spectrum with that of a standard PVA sample (Figure 17a and b).\textsuperscript{159}

A complete scheme for separating dissolved and colloidal substances, including stickies, from recycled waste paper was recently described by Holmbom.\textsuperscript{160} After centrifuging to remove fibers and other particles, one portion of the sample was analyzed for carbohydrates, uronic acids, and pectins, using methanolysis, followed by GC of silylated derivatives. A second portion was extracted with MTBE. The MTBE phase was analyzed by GC for various lipophilic compounds and lignans. For

the analysis of stickies, a pulp, paper, or process liquid sample was freeze-dried and refluxed in THF, filtered and the extract was then fractionated by HPLC/SEC. A typical chromatogram of THF extracts of a deinked pulp sample is shown in Figure 18. Each SEC fraction was then analyzed by py/GC/MS. Pyrolysis components in the polymeric fraction are shown in Table 10.

Analytical schemes have also been devised for the analysis of metal soaps\textsuperscript{158,161} and defoamers\textsuperscript{162} in pitch deposits. Calcium and aluminum soaps of fatty acids, because of their highly sticky nature, can enhance the deposition of other components in pitch deposits, and are therefore considered to play an important role in the deposition process. The scheme developed by Dorris et al.\textsuperscript{161} for analysis of calcium soaps in kraft mill brownstock pitch deposits involves extracting the deposit with acetone to remove free acids and neutrals. The acetone-extracted deposits were then Soxhlet extracted with chloroform to remove calcium soaps. The chloroform extracts were subsequently filtered to separate the soaps from material insoluble in cold chloroform. The types and amounts of acids bound to calcium ions were also determined by hydrolysis of calcium soaps followed by analysis of the liberated acids by capillary GC. This scheme was modified for aluminum soaps because the latter are partially soluble in hot acetone and chloroform.\textsuperscript{158} In this case, the initial extraction with acetone was conducted at room temperature to remove wood resin and hydrocarbon oil. This was followed by refluxing with acidic acetone to yield metal-bound acids and aluminum chloride precipitate. The aluminum was then determined by AAS, and the acids were analyzed by GC and GC/MS. The complete scheme, shown in Figure 19, was applied to the determination of aluminum soaps in newsprint mill deposits. For the analysis of amide defoamers,\textsuperscript{162} another potential contributor to pitch deposits, the approach taken was to extract the deposit with chloroform, followed by isolation of the fatty acid diamides, the active ingredient of amide defoamers, by recrystallization and filtration. The mineral oil, one of the main ingredients of defoamers, was separated by adsorption chromatography on silica gel. The fractionation scheme for isolating mineral oil and diamides from pitch deposits is illustrated in Figure 20.

The use of $^{13}$C-NMR for the analysis of pitch extracts has been reported by Suckling and Ede.\textsuperscript{163} The method can be used to determine quantitatively the amounts of triglycerides, fatty and resin acids, and esters. The technique is nondestructive and allows one to assess whether other organic components such as defoamers and retention aids are present. However, it requires more than 1 g of sample for analysis, and only material completely soluble in the solvent used for NMR spectroscopy can be analyzed. Proton NMR spectroscopy has also been used for the characterization of synthetic polymers in a pitch deposit\textsuperscript{164} and, in combination with GC and SEC, for the analysis of so-called white pitch deposits, originating from coated papers.\textsuperscript{165}

Another relatively new hyphenated technique for identifying the source of contaminants in mill samples is thermogravimetry (TG)/IR/MS.\(^{166}\) The loss of weight by TG allows one to determine the proportion of organics in the sample, and analysis of the volatile material can be achieved by IR spectroscopy, followed by MS. This combination of techniques was used to determine a variety of contaminants in mill deposits, including common sizing agents, AKD and ASA, and a residual surfactant, a dimethyl-substituted amine, which was interfering with the sizing process. The technique is relatively rapid and requires only a few milligrams of sample with minimal preparation prior to analysis.

Py/GC is a particularly well-suited technique for identification of synthetic polymers in complex mixtures.\(^{167,168}\) It requires as little as 1 mg of sample for analysis and no sample preparation. A fingerprint of a particular polymer can often be obtained from its fragmentation pattern. This is illustrated in Figure 21(a) and (b), which shows pyrolysis chromatograms of a contaminant in the dryer section of a tissue mill and of a PVA standard.\(^{168}\) The similarity between the two chromatograms is evident, and suggests that the contaminant originates from PVA which was introduced with the recycled wastepaper. Even complex mixtures can be analyzed by careful manipulation of the pyrolysis and chromatographic conditions. However, in such cases, identification of the various components is best carried out by combining MS with py/GC, as described by Hardell\(^{169}\) and del Rio et al.\(^{170}\)

Analysis of spots and specks in pulp and paper can also be conveniently carried out by IR spectroscopy. The technique is rapid, and can be performed on sub-millimeter specks with little or no sample preparation. It is especially useful for identifying relatively pure contaminants or those consisting of a few major components. Leclerc et al.\(^{171}\) showed the application of diffuse reflectance infrared Fourier transform (DRIFT) spectrometry to the characterization of plastic and other contaminants, including polyethylene, polypropylene, and latexes in pulp, and more recently to the identification of wood resins, metal soaps, talc, clay, and defoamers in pitch deposits and dirt specks from market kraft pulp.\(^{172}\) The use of a miniature diamond anvil cell is particularly convenient for FTIR analysis, in the transmission mode, of dirt specks and spots, as described by Douek and Guo.\(^{159}\)

9 CONCLUSION

This overview of the major types of chemical analyses conducted on pulp and paper matrices is by no means exhaustive. Owing to space limitations, only a relatively few publications, representative of each area of pulp

and paper analysis, could be cited. The intention was to provide the reader with a sense of the broad scope

of analytical techniques and instrumentation used in the pulp and paper field. The analyses described in this article range, in fact, from the traditional wet-chemical and instrumental methods designed primarily for routine testing in mills to highly sophisticated techniques used mainly for research purposes. As new analytical developments and measurement tools become available, some of these will no doubt continue to find their way into pulp and paper mills and research laboratories.

Pyrolysis in the Pulp and Paper Industry

B. Bruce Sitholé
Pulp and Paper Research Institute of Canada, Pointe Claire, Canada

1 Introduction

Pyrolysis techniques involve the application of thermal energy to induce the transformation or degradation of compounds. The techniques can be divided into two types, applied pyrolysis and analytical pyrolysis. Applied pyrolysis is concerned with the production of chemicals, e.g. the pyrolysis of coal to generate oil. Analytical pyrolysis deals with the structural identification and quantitation of pyrolysis products with the ultimate aim of establishing the identity of the original material and the mechanisms of its thermal decomposition. This article is devoted to analytical pyrolysis.

Pyrolysis techniques involve the application of thermal energy to induce the transformation or degradation of compounds. The techniques can be divided into two types, applied pyrolysis and analytical pyrolysis. Applied pyrolysis is concerned with the production of chemicals, e.g. the pyrolysis of coal to generate oil. Analytical pyrolysis deals with the structural identification and quantitation of pyrolysis products with the ultimate aim of establishing the identity of the original material and the mechanisms of its thermal decomposition. This article is devoted to analytical pyrolysis.

Many organic compounds can be analyzed by GC, provided that they are volatile or can be derivatized into compounds that are amenable to analysis by GC. Compounds that cannot be analyzed by GC can instead

Analytical pyrolysis is a powerful technique that is seldom used in the pulp and paper industry. This article illustrates the utility of the technique to study the chemistry of wood and pulps, mechanistic aspects of pulping, troubleshooting process upsets in pulp and papermaking, and evaluating the quality of finished products. The technique has advantages over other analytical techniques in that little sample preparation is required and enough data can be obtained from very small amounts such as dirt spots on paper. In many cases good data can be obtained by analyzing the pyrolysis products by gas chromatography (GC) with flame ionization detection (FID). Detection with mass spectrometry (MS) offers the advantage of absolute qualitative and quantitative determination of the chemistry of the analytes. In many instances the chromatography can be improved by on-line derivatization of the pyrolysis products with an alkylation agent.

This article takes the reader through a survey of the different types of analytical pyrolysis systems, through data analysis and processing, and examples of applications of analytical pyrolysis in the pulp and paper industry. Ample illustrations are used to highlight the usefulness of the technique.

1 INTRODUCTION
be analyzed by other chromatographic techniques such as liquid chromatography and capillary electrophoresis. The analysis of many polymers by any of these analytical techniques tends to be difficult mainly because they require that the analytes be brought into solution, and this is usually difficult to achieve. Such compounds are candidates for analytical pyrolysis, which entails applying thermal energy to break them into products that are volatile enough to be analyzed by GC. If the pyrolysis is done under controlled conditions and inert atmospheres, the resultant pyrolysis fragments give characteristic patterns that are “fingerprints” of the original polymers. Further information on the chemistry of the fragments can be obtained by detecting them by MS and, in some instances, by Fourier transform infrared (FTIR) spectroscopy. The pyrolysis can be done by rapid heating (flash pyrolysis) or temperature-programmed heating (slow pyrolysis) of the polymers. Slow pyrolysis products can be sent to a mass spectrometer or the pyrolysis can be done directly in a mass spectrometer.

Although there are a number of books and reviews on analytical pyrolysis techniques, e.g. an introduction to pyrolysis,(1) a bibliography,(2) an applications monograph,(3) a handbook,(4) and an extensive bibliography of 594 references on synthetic polymers,(5) there do not seem to be any that are specifically targeted for pulp and paper matrices (e.g. none of the 11 chapters in the handbook edited by Wampler(4) specifically address pulp and paper analysis). This article addresses this shortcoming by reviewing how pyrolysis techniques are aptly suited to the analysis of samples from the pulp and paper industry. The pyrolysis techniques are useful in understanding mechanistic aspects of natural polymers present in wood, and how they affect pulp and papermaking processes. They can also be used to optimize pulp and papermaking processes and to troubleshoot production and product quality problems. This review will include applications of pyrolysis/mass spectrometry (Py/MS), pyrolysis/Fourier transform infrared (Py/FTIR) spectroscopy, pyrolysis/gas chromatography (Py/GC), and pyrolysis/gas chromatography/mass spectrometry (Py/GC/MS), but the main emphasis will be on the last two techniques. Theoretical aspects of pyrolysis are beyond the scope of the article but can be found in the references listed above.

Since the pyrolysis unit, the pyrolyzer, is the heart of analytical pyrolysis, it is important to understand how pyrolysis is achieved. The next section reviews the different pyrolysis modes that are currently available.

2 INSTRUMENTATION

Analytical pyrolysis can be looked upon as occurring in two steps, namely fragmentation of the sample to be analyzed and detection of the pyrolysis products by a suitable detector. In general, lower pyrolysis temperatures cause less fragmentation, resulting in smaller amounts of pyrolysis products. Very low pyrolysis temperatures may not cause fragmentation of samples but may remove volatile matter that may interfere in the interpretation of the pyrograms. For example, poly(vinyl chloride) contains residual softening agents and antioxidants that can be removed by thermal desorption. Higher temperatures can result in extensive fragmentation of samples resulting in larger amounts of pyrolysis products and more complex pyrograms that may be difficult to interpret by the detector used. This can be solved by introducing an extra step in the analytical pyrolysis procedure, namely separation of the pyrolysis products by GC.

After pyrolysis, the fragments are swept on to a chromatographic column. Typically, an inert gas, helium, is used to flush the pyrolyzer at high flow rates (50 mL min⁻¹ and above), thereby avoiding recombination of the fragments. The chromatographic process separates the fragments according to their volatility. Usually, the column is maintained at a low temperature at the beginning to allow condensation of the pyrolysates into a narrow plug at the head of the column. The highest sensitivity is achieved by direct flow without splitting, but normally an appropriate split ratio is used to avoid overloading the column and to induce a reasonable flow rate during the chromatographic process. The separated pyrolysis products can then be detected by a suitable detector such as a FTIR spectrometer, flame ionization detector, or mass spectrometer. The last two are the most common types of detection and will be the focus of this article. Analytical pyrolysis requires that the sample be heated to pyrolysis temperatures in a reproducible manner. The reproducibility of fragmentation patterns is determined by parameters such as mode of heating, sample size, sample preparation, and flow rate. For example, large samples may experience temperature gradients during pyrolysis and this will result in the generation of irreproducible pyrograms. Also, pyrolysis of large samples may result in contamination of analytical columns, especially the inlet side. Back rinsing of the column with solvents or cutting off a small portion of the column (~30 cm) can restore the performance of capillary columns. Other techniques that have been employed to avoid contamination of columns include installation of disposable precolumns (similar to what is done in high-performance liquid chromatography), design of a splitter system to reduce column contamination without affecting the performance of the chromatographic column, and modification of the Py/GC inlet system for capillary columns to allow proper identification of the pyrolysis products, including those with lower volatilities that remain in the pyrolysis chamber. Analysis of standards at regular intervals is a
A good way of ensuring that a Py/GC system is generating reproducible pyrograms.

Analytical pyrolysis has traditionally been carried out using laboratory-made instruments and this has made it difficult to develop standardized instrumentation. Also, the technique has been practised in so many different ways that it has resulted in a bewildering array of terms and terminologies. An attempt was therefore made to develop a common nomenclature.(9) The nomenclature is listed in Appendix 1. Later, the International Union of Pure and Applied Chemistry (IUPAC) published recommendations entitled “Nomenclature and Terminology for Analytical Pyrolysis”.(10)

A good pyrolysis unit should meet certain specifications, such as a very low dead volume and a short and heat-insulated connection between the pyrolyzer and the detector or GC column to prevent condensation of high-boiling pyrolysis products, rapid heating of the sample, and accommodation of different sample forms. The variety of instrumentations used can be categorized into three kinds, namely isothermal furnace pyrolyzers, Curie point (inductively heated filament) pyrolyzers, and resistively heated pyrolyzers. Features and operations of each type of pyrolyzer will be described below. The different modes of sample heating in the three modes of pyrolysis designs imply that the resultant pyrograms may be different from one instrument to another. Such discrepancies therefore require that care should be taken when comparing pyrograms from different pyrolysis systems.

2.1 Isothermal Furnace Pyrolyzers

In this class of pyrolyzer, the furnace is held isothermally at a specific temperature, typically the pyrolysis temperature, and the sample is introduced into the hot furnace. A carrier gas at a high flow rate is used to sweep the pyrolysis products onto a chromatographic column for analysis. Figure 1 is a schematic of the apparatus.

In most cases, a liquid sample in a syringe is injected into the hot zone where it vaporizes before undergoing pyrolysis. The inlet carrier gas rapidly sweeps the pyrolysis products on to the chromatographic column. Typically, high inlet gas flows, e.g. 50 mL min⁻¹, are used. One therefore has to be careful that the sample in the syringe is not swept out of the needle housing during the injection process. Solid samples can be introduced by prior dissolution of the samples in suitable solvents or the use of syringes designed for injection of solid samples. There are two designs of such syringes. In the first design, one needle resides inside another needle. After the solid sample has been placed on a groove or indentation of the inner needle, the syringe is then injected into the pyrolyzer and the plunger depressed to expose the contents of the inner needle to the hot furnace. In the second design, the injector is supplied with two interchangeable plungers: a spiral tip plunger for injecting solids and a flat-tipped plunger for solid samples in the form of granules, fibers, or powders that can be packed into the bore of the needle with the plunger retracted. A pelletizer can be used for producing micropellets that can be transferred into the bore of the solids injector. One manufacturer (Shimadzu) has a unique sample dropping method that is said to shorten the time of heating the sample to the decomposition temperature and to minimize the loss of the low-boiling components. Consequently, all of the pyrolysis products load on to the GC column at a faster rate.

A heating coil wrapped around the furnace is used to heat the furnace to a specified temperature and a temperature sensor sends a signal to a controller that adjusts the conditions to maintain a constant temperature. The wall thickness and insulation of the furnace affect the time required to reach a set temperature equilibrium. The pyrolysis temperature experienced by the sample may not be the same as that of the furnace because of temperature gradients induced by the wall thickness of the sample holder, the flow rate and the size of the sample. The simple nature of isothermal pyrolyzers implies that they are easy to construct in-house as they do not require sophisticated controls. The pyrolyzers are ideal for situations that do not require frequent changes of pyrolysis temperature or temperature gradients.

Furnace pyrolyzers tend to be large and cumbersome and require inordinately long times to reach equilibrium temperatures. Their pyrolysis tubes are also large and thus it is not easy to ascertain the actual pyrolysis temperatures of the analyzed samples. The pyrolyzers require large amounts of samples and are inconvenient for cases where the sample size is limited, e.g. dirt spots on paper. A splitter inside the GC housing reduces the flow rate to the
carrier gas in (He) to column

Figure 2 Schematic of a modified microfurnace pyrolyzer.

column to normal analytical flow rates, and is maintained at the highest temperature that will be experienced by the chromatographic column.

A more recent design of the pyrolyzer is a microfurnace unit that can analyze small samples of about 100 µg. In the unit, shown schematically in Figure 2, the sample for analysis is placed in a platinum cup that is held above the pyrolyzer at room temperature (position I). Lowering of the sample to position II allows for pyrolysis of the sample. This arrangement is claimed to be suitable for labile compounds because the sample is not exposed to high temperatures before the pyrolysis step.\(^{(1)}\)

2.2 Curie Point Pyrolyzers

Figure 3 shows a schematic of a Curie point pyrolyzer. Here the active heating element is a ferromagnetic metal wire that is placed in a radiofrequency field to induce eddy currents. The Curie point temperature reached depends on the type of metal used: the values for cobalt, nickel, and iron are 1128, 359, and 770 °C, respectively. These values are specific for the metals in question and can only be altered by making alloys of the metals. For example, a nickel–iron alloy wire common in many Curie point systems reaches a maximum at 510 °C. A series of ferromagnetic alloys are available with temperature ranges from 160 to 1040 °C. Ballistic heating enables the pyrolysis temperatures to be reached within 20–30 ms. The sample, typically 10–20 µg, is coated on the wire, and is then dried while rotating the wire. Application of the sample as a melt which then solidifies on the wire can be used for coating the wire. Reproducible coating of samples on the wire is essential to ensure the production of pyrograms that are fingerprints of the samples to be analyzed. Samples that are difficult to coat on the wire can be introduced by bending, flattening, or crimping the wire, or by making indentations on the wire that will retain the samples.

Deterioration of the sample wires with usage will eventually affect the reproducibility of the pyrograms generated by the system. Cleaning of all components that are in contact with the sample and pyrolysis products is essential for long-term reproducibility. The cleaning can be done by scrubbing or sanding or by cleaning with acid and/or solvent. Heating at elevated temperatures such as in a flame for a few seconds is ideal for removing deposits that are difficult to remove by other cleaning methods. However, pyrolyzer components that are susceptible to oxidation should not be heated in a flame.

Curie point pyrolyzers can be automated with multichannel autosamplers that allow for automatic and unattended analysis of up to 24 samples. For example, DyChrom (Santa Clara, CA, USA) markets a unit that can be used with 20 different ferromagnetic alloy wires to cover temperature range from 160 to 1040 °C.

Curie point pyrolyzers are considered inferior to microfurnace pyrolyzers because they cannot maintain accurate and high oven temperatures at their outlets ends attached to gas chromatographs. Consequently,
Figure 4 Comparison of pyrograms generated with (a) normal and (b) modified Curie point pyrolyzers.

high-molecular-weight fragments such as styrene trimers are lost and not readily detectable by pyrolysis using a Curie point analyzer. These shortcomings were apparently overcome by the development of a Curie point pyrolyzer with a modified maintenance oven that allows adequate transfer of high-molecular-weight fragments into the GC analytical column. Figure 4(a) and (b) illustrate the advantage of such a modified pyrolyzer; it is evident that the modified pyrolyzer facilitates the detection of pyrolysis fragments of polypropylene with chain lengths exceeding C36. Chromatography of styrene trimers, from pyrolysis of polystyrene, was significantly improved using this analyzer.

2.3 Resistively Heated Pyrolyzers

The principle of resistively heated pyrolyzers (or filament probes) entails rapid heating of a sample from ambient to pyrolysis temperature in a matter of milliseconds and this is achieved by applying an electrical current to a filament that holds either the sample or a tube that contains the sample. An early design of such a system featured a ribbon or coil that was an element in a Wheatstone bridge. The bridge was set such that when balanced at the pyrolysis set-point temperature a capacitor was discharged to rapidly heat the filament to a temperature of 1000 °C at rates of 20 °C ms⁻¹. Modern designs can now heat at rates that vary from 0.01 °C min⁻¹ to 30 °C ms⁻¹. The filaments used exhibit high electrical resistance and wide operating temperatures and they can be made of iron, platinum, and Nichrome. They can be configured as either a ribbon for direct sample placement or as a coil for holding samples in reusable quartz tubes or boats.

The absence of a barrier between the sample and a ribbon filament ensures good contact between the sample and filament, thus enabling rapid heating of the sample. In one design, shown schematically in Figure 5, two current pulses of variable time and amplitude are applied to the filament during pyrolysis: the first heats the filament to the set pyrolysis temperature and the second compensates for cooling effects to enable the sample to experience the same temperature during the entire pyrolysis time. The cooling effects are induced by a fast gas flow that sweeps the pyrolysis products on to the chromatographic column. Thus the current pulses control the length and shape of the computer-generated temperature and time profiles, thereby guaranteeing accuracy and reproducibility. This is considered critical as temperature affects the generation of pyrolysis degradation products. The rapid heating minimizes decomposition of the sample during the temperature rise time (TRT). The pyrolysis time can be changed according to the size of the sample to prevent overheating of the filament after sample pyrolysis; such overheating may lead to unwanted secondary decomposition of the pyrolysis products. The pyrolysis temperature can be monitored in two ways: electrical resistance of the filament and filament light emission of the filament/sample contact area. Both can be displayed and compared on a screen or downloaded to a printer. The comparison is done to confirm the reproducibility.
of the pyrolysis profile. Such a pyrolyzer is believed to be well suited for quantitative analysis because of the rapid heating under very reproducible conditions.\(^{14,15}\) However, the filaments used are very thin and fragile and they break if current is applied to them in the absence of a gas flow. Residual pyrolysis products on the filaments need to be removed by heating over a flame. Each time they are replaced, the system has to be calibrated to ensure that the correct pyrolysis profiles will be attained. In some designs, the filaments come in precalibrated cases, and an optical output will read the correct temperatures.

Coiled filaments are more rugged than ribbon filaments. Since they are not in direct contact with analytes, they are consequently not contaminated by pyrolysis products or nonpyrolyzed matter and therefore do not require cleaning. These filaments can last for very long periods before replacement.

The filament probes are housed in heated chambers to minimize condensation of the pyrolysis products. The high pyrolysis temperatures in resistively heated pyrolyzers can result in deposition of pyrolysis products on the walls of the chambers that are at lower temperatures. To prevent such contamination, the chambers can be lined with quartz or the filament can be housed in reusable quartz tubes. The use of quartz also minimizes catalytic and secondary reactions that occur on hot metal surfaces.

The filament probes were originally interfaced to GC injection ports by attaching a heated interface to the septum retainer of the gas chromatograph. Carrier gas was then passed through the heated chamber into the injection port via a needle assembly. When the probe was removed and reloaded for each run, air was introduced into the column with undesirable consequences especially for MS detectors. This problem has now been overcome by valved interfaces that isolate the GC injection port from the pyrolysis probe so that the probe can be removed or inserted without interrupting the carrier flow in the gas chromatograph.

Filament probes are ideally suited for sequential pyrolysis where a sample is heated at one temperature to pyrolyze interfering compounds and at a higher temperature to pyrolyze the analytes of interest. Examples of applications of this technique will be discussed later in section 5. An example of the reproducibility of a resistively heated pyrolyzer is shown in Table 1 for the pyrolysis of polystyrene. Polystyrene is often used to check the reproducibility of a pyrolyzer because its pyrolysis products vary from low- to high-boiling components and the main products are styrene monomer, dimer, and trimer, as illustrated in Figure 6. The data in Table 1 show that the relative standard deviation is within 2%.\(^{16}\)

### 2.4 Thermal Extraction Pyrolyzers

Humble Instruments (Humble, TX, USA), markets a flow-programmable thermal extraction/pyrolysis injector that is said to offer true, in-sample temperature measurement for the accurate study of the decomposition of complex samples. The unit can be used for vaporization (thermal extraction) and nonisothermal (constant heating rate) pyrolysis of solid or liquid samples. Thermal extraction GC is a solvent-free technique for fingerprinting the volatile components present in solid or liquid samples. Volatile compounds are thermally volatilized from the sample matrix into a GC oven where they are cryogenically focused on-column resulting in well-resolved peaks (this is equivalent to syringe injection of the volatile sample). This technique should be applicable to the analysis of volatile and odorous materials in pulp and paper matrices. Thermal extraction at high temperatures, usually from 340 to 650 °C, can be used for the analysis of high-molecular-weight compounds such as polymers. The pyrolyzer can also be used to automatically acquire multiple heating rate cycles with true temperature acquisition for kinetic determinations. Pyrolysis profiles consisting of time, true temperature acquisition, and rate (FID

response) are processed using one of the kinetic models in Lawrence National Laboratory's Kinetics® program. However, the pyrograms generated may be different from those obtained with other pyrolyzers because of the non-isothermal pyrolysis conditions.

The unit can be equipped with a microscale sealed vessel for the generation of closed-system pyrolysis products. The vessel is a 40 µL glass tube that may be sealed after sample and internal standard loading. The tubes are heated under tightly controlled conditions. Products generated by this pyrolysis technique do not contain the intermediate reactants formed during open-system, nonisothermal, or flash pyrolysis.

2.5 Off-line Pyrolysis/Gas Chromatography

In off-line Py/GC, the pyrolysis is done in the absence of a chromatograph and the pyrolysis products are trapped for subsequent analysis by GC or gas chromatography/mass spectrometry (GC/MS). A typical experimental set-up is shown in Figure 7. The apparatus is flushed with an inert gas (helium) before pyrolysis of the sample that is placed between silanized quartz wool packing in a quartz tube. The quartz wool allows the pyrolysis products to pass through but traps nonpyrolyzed compounds that may be swept by the gas flow. The pyrolysis products condense in the quartz tube that is cooled with liquid nitrogen. After pyrolysis, the pyrolysis products condensed in the quartz tube are rinsed with a suitable solvent and analyzed quickly to minimize time-dependent secondary reactions.

2.6 Pyrolysis/Mass Spectrometry

In Py/MS, a mass spectrometer detects the pyrolyzed compounds. The pyrolysis probe is inserted directly in the mass spectrometer. This offers advantages such as collection of repetitive scans during the pyrolysis, detection of different decomposition steps of the analyte, detection of thermally labile compounds because of the vacuum conditions in the mass spectrometer, and detection of high-molecular-weight compounds. High-molecular-weight compounds can be detected because there is no interface between the pyrolyzer and the mass spectrometer (in Py/GC/MS high-molecular-weight materials are lost by adsorption on the walls of the interface surfaces). Disadvantages of Py/MS are that the technique detects mixtures of pyrolysis products and further analysis of the mass spectra is required to identify each pyrolysis product. Also, quantitative analysis of the pyrolyzed components is difficult.

2.7 Pyrolysis/Fourier Transform Infrared Spectroscopy

In Py/FTIR spectroscopy, the pyrolysis products are directed to an infrared (IR) cell. In early designs, pyrolysis was done in a test tube and the pyrolysis products were condensed or deposited on an IR-transparent plate or crystal. This, however, resulted in recombination of the pyrolysis products and consequently did not give an accurate view of the pyrolysis process. This limitation was partially solved by use of a heated transfer line to transport the volatiles into the IR beam. The procedure resulted in dilution of the pyrolyzed products that were therefore difficult to detect. Direct-pyrolysis FTIR spectroscopy overcomes these problems because the sample is located <3 mm below the IR beam via a specially designed interface. The interface, a cylindrical cell with windows on each end, houses the pyrolysis probe. Upon pyrolysis, the volatiles diffuse immediately into the IR beam where they are detected. The sensitivity is very good with this technique because of minimal sample dilution. Samples may also be heated at slow rates (e.g. 0.01 °C min⁻¹) to carry out time-evolved studies and simulated distillations. Several variables can affect the accuracy of the results obtained by direct Py/FTIR spectroscopy. They include pyrolysis temperature, cell temperature, and the flow rate of the gas through the pyrolyzer. Cell temperature is important to prevent condensation of the pyrolysis products on the cell windows. The gas flow rate can be optimized to provide adequate ventilation without losing sensitivity. The optimized parameters for one commercial Py/FTIR instrument are a cell temperature of 200 °C and a cell flow rate of 40 mL min⁻¹.

Py/FTIR spectroscopy is ideal for clean samples or mixtures whose components pyrolyze at distinct temperatures. The technique is more rapid than Py/GC because the chromatographic step is eliminated. Thus in cases where one is concerned with quality control of materials, such as paper coating formulations, Py/FTIR would be the method of choice over Py/GC.
2.8 Automated Analytical Pyrolysis

In the majority of cases, pyrolyzers are marketed by companies that do not manufacture gas chromatographs. This sometimes poses a problem in ensuring that a pyrolyzer will be able to communicate properly with a GC column to which it is attached. For example, triggering a GC run should simultaneously trigger the pyrolyzer. This can be accomplished by modification of the electronics of the GC system, provided that this will not negate the warranty of either instrument. Another potential problem may be conflict in the software of the two systems: GC vendors normally warranty only their software running on the GC systems that they sell. Pyrolysis products fouling mass spectrometers are considered the fault of the operator even though the pyrolysis system in use may have been faulty. Understandably, the vendor of the pyrolysis unit will not take responsibility for the mass spectrometer. These problems could be avoided if companies made complete dedicated pyrolysis GC/MS systems. Dutch researchers developed the first fully integrated pyrolysis mass spectrometer in the 1970s by integrating a Riber quadrupole mass analyzer with a Curie point pyrolyzer. Further development led to the production of a fully automated system that utilized high-speed ion counting and computerized data-processing techniques. This advance resulted in the development of two commercial instruments, the Extranuclear 5000 from Extranuclear Laboratories (USA) and the Pyromass 8-80 from VG Gas Analysis (UK). The two instruments were based on conventional MS and, consequently, were very expensive for most laboratories. A low-cost dedicated instrument was developed in the mid 1980s. The instrument came with a microcomputer that was capable of performing on-line pattern recognition analysis. Currently, there is a dedicated Py/GC/MS system that has found wide use in the microbiological field. The instrument, marketed by Horizon Instruments (East Sussex, UK), is an automated and dedicated Py/GC/MS system that can process 150 samples unattended. It also uses a Curie point pyrolyzer and a quadrupole mass spectrometer with a mass range of 12–400 Da. Another dedicated system is available from Shimadzu Scientific Instruments (Maryland, USA). It is a furnace pyrolyzer attached to a gas chromatograph with a quadrupole mass spectrometer. The system, however, does not have autosampling capabilities.

Automation in resistively heated pyrolyzers is difficult, if not impossible, in systems that use ribbon filaments. This is because the filament has to be cleaned after each pyrolysis run to remove pyrolysis products of the previous run. In cases where the filament is a coil, automation is possible because a fresh tube is brought into the coil before each pyrolysis run. For example, CDS Analytical (Pennsylvania, USA) has an automated pyrolysis unit that can run 36 samples. The unit is equipped with software that enables control of the pyrolysis probe and programming of the autosampler. The samples, placed in 2 × 40 mm quartz tubes, can be loaded on a carousel that feeds the samples on to the pyrolyzer by gravity. The pyrolyzer, equipped with a platinum filament coil, has five sensors for monitoring the home and carousel number locations, the tray used, presence of sample tube, and discharge of the tube from the pyrolyzer. Cleaning of the pyrolyzer can be done by valving to the gas chromatograph for blank runs or out to vent to remove contaminants.

3 DATA ANALYSIS

Pyrolysis under controlled conditions results in the production of pyrolysis products that are often used to fingerprint the nature of the original sample. Thus an unknown pyrogram can be identified by comparison with standards run under the same conditions. In cases where only a few pyrolysis products are generated the comparison can be made visually, e.g. by overlaying pyrograms. However, visual comparison tends to be complicated in situations where pyrolysis results in large numbers of pyrolysis products. In such cases, multivariate data analysis may yield more information than visual comparison. Multivariate data analysis is considered useful in evaluating data that contains correlated variables as in the pyrolysis of pulp and paper matrices where such pyrolysis results in degradation products that can be correlated with constituents in the pyrolyzed matrices. Theoretical treatises on multivariate data analysis have been reported. The analysis reduces a large amount of complex data down to a form where it can be readily understood, e.g. graphical output in two or three dimensions. Two statistical methods that can manipulate data to show correlations are principal component analysis (PCA) and partial least squares (PLS).

PCA is used to identify correlations within large data sets and to reduce the number of dimensions required to display the variation within the data. A new set of axes, principal components, is constructed, each of which accounts for the maximum variation not accounted for by previous principal components. With pyrolysis mass spectra, PCA is used essentially as a data reduction technique prior to performing PLS analysis. The information obtained from principal component plots can be used to identify samples that deviate from the norm and/or outliers within the data and as a test for reproducibility.

The PLS method finds correlations between the principal components and generates new vectors based on two principles: a good approximation of the separation
between the variables and the highest correlation possible between the variables.

Both methods generate their models with an internal validation of significance called cross-validation: parts of the data are kept out of the model development, and then predicted by the created model and compared with the actual values.

Discrimination of similar pyrograms can be done by comparison of individual peaks in the pyrograms. For example, Meier et al.,$^{26}$ used a software package, called MatchFinder®, that is designed for analysis of complex pyrograms. The program analyzes retention times and responses (peak areas or heights) of each peak in the pyrogram. Initially, trial assignments are made to determine if there are any peaks in the pyrograms that correspond to each other. An annealing algorithm is then used to avoid suboptimal solutions. The matching process is rapid, typically 3–4 min. An overall measure of the similarity between pyrograms is indicated by the “match quality”. Analysis of the Py/GC data by computer base discrimination methods showed that the origins of teak, mahogany, and eucalyptus could be discerned but it was not possible to determine the origin of pine wood samples.

### 3.1 Fingerprinting of Samples

When heated to pyrolysis temperatures, polymers dissociate at certain bonds, resulting in degradation products, usually monomers, that may rearrange to form dimers, trimers, and other derivatives of the monomer. The amounts and ratios of these degradation products are a function of the pyrolysis temperature. For example, pyrolysis of polystyrene at three different temperatures results in the generation of mainly monomers, dimers, and trimers whose ratios vary with the pyrolysis temperature.$^{27}$ This is illustrated in Figure 8(a–c) for pyrolysis of the polymer at 600, 700 and 800 °C: the amount of trimer generated decreased with increase in temperature and very little is produced at 800 °C. The patterns of the pyrograms shown will be reproducible if the pyrolysis conditions can be controlled to strict tolerances. These resultant pyrograms can then be used to “fingerprint” the pyrolyzed polymer. The fingerprinting is different from that generated by IR data in that the pyrolysis conditions influence the pattern of the pyrograms. Although other parameters such as the instrument used, sample size, and geometry may also influence the pyrogram pattern, Py/GC has found widespread use in fingerprinting a wide variety of polymers.$^{4,28,29}$

Fingerprinting is usually easy when dealing with pure polymer samples where there are no interferences from sample matrices. Complications arise when analyzing complex multicomponent samples that may be partly organic materials having different melting points.

Pyrograms from such matrices are so complex that it is difficult to discern the nature of the components present. However, this can be overcome by multistep pyrolysis that permits selective volatilization of individual components from the sample or division of the sample into temperature-dependent fractions. For example, interferences from cellulosic products in the pyrolysis of paper samples can be overcome by a two-step procedure: at one temperature to volatilize the cellulosic products and at a higher temperature to pyrolyze the polymer(s) of interest.$^{30,31}$ Simultaneous pyrolysis derivatization techniques can also be used to minimize matrix interferences, as will be discussed later in this article.

Determining the origin of wood species is an important and desirable thing to do because different wood species have different characteristics such as fiber length, fiber wall thickness, and wood resin content. These characteristics will affect the pulp and papermaking properties of the woods. Conventional methods for differentiating wood species involve macroscopic and microscopic techniques. However, the techniques are not capable of detecting small differences between same species that may be induced by the environmental conditions where the trees grew. Analytical pyrolysis may be used to fingerprint different wood species. For example, it can be used to distinguish softwoods from hardwoods, in that the pyrograms of their wood extractives are different: softwood extractives
will show the presence of resin acids and fatty acids whereas hardwoods will contain fatty acids sterols and sterol esters but no resin acids.\(^{(32)}\) In another example, pyrolysis of acetone extracts of *Eucalyptus* species shows the presence of fatty acids, \(\beta\)-sitosterol, sitostanol, fucosterol, saturated and unsaturated fatty acids, and \(\alpha\)-tocopherol.\(^{(33)}\)

A comprehensive study was undertaken to differentiate wood species from different areas by using Py/GC, Py/MS, near-infrared (NIR) spectroscopy, and multivariate data analysis.\(^{(26)}\) The wood species studied and their origins are shown in Table 2. For Py/GC work a resistively heated probe was used, whereas a Curie point pyrolyzer was used for Py/MS studies. Pyrolysis of the samples gave complex data that were evaluated using a dynamic chromatographic profile matching algorithm for Py/GC studies and chemometric methods for data reduction in the case of Py/MS studies.

The MS raw data and results for multivariate analysis, PCA, and canonical variates analysis of the MS data obtained by Py/MS showed that there was good reproducibility within a group, as demonstrated by the closeness of the points in each group. This therefore demonstrated that Py/MS can be used to differentiate wood species harvested in different areas.

The pyrograms obtained by Py/GC were processed via a software package, MatchFinder\(^{(34)}\), that compares pyrograms by evaluating the retention times and responses of each peak in the pyrograms. Figure 9(a–h) show the match qualities of the wood samples analyzed, in duplicate, by Py/GC. It is clear that the reproducibility is not very good for the duplicates, except for the pine wood samples. In addition, the discrimination of samples is not as clear as with Py/MS analysis.

### 3.2 Pyrolysis/Gas Chromatography/Mass Spectrometry Library

The need for a library of pyrolysis mass spectra has been recognized since the early days of analytical pyrolysis, but progress has been slow owing to the complex pyrograms generated. In 1985, Italian researchers described a library of mass spectra of polymers containing 200 entries.\(^{(34)}\) The spectra were obtained by direct Py/MS (electron impact) that entailed heating the polymers in the direct insertion probe of a mass spectrometer, at a constant heating rate and recording the repetitive mass spectra during the temperature rise time (TRT). The library could be used both as a database for library searches and as a training tool for pattern recognition analysis. Two pattern recognition methods used on the library produced identical results. A major limitation of the library is that the spectra were generated on fragments produced by heating in a direct insertion probe. The absence of chromatographic separation of the pyrolysis fragments implies that only pure polymers could be analyzed and identified by the library. Analysis of unknown mixtures that produce complex spectra would be difficult to identify using the library.

Matheson et al.\(^{(35)}\) are creating a computer library for the identification of polymers by Py/GC/MS, the aim being eventually to encompass most known polymers. Since Py/GC/MS total ion chromatograms are complex, it is obviously time-consuming to look at individual peaks in a pyrogram for identification purposes. The library under creation uses a scheme that selects peaks that are crucial to the identification of unknown compounds; these are then compared with known spectra, thus simplifying the analysis of the compounds.

It has been mentioned earlier that pyrolysis conditions will affect the resultant pyrograms and that different pyrolyzers may yield differing pyrolysis products. Therefore, a first step in the creation of the library was the selection of Py/GC/MS conditions. Using a pulse pyrolyzer, pyrograms were generated at three temperatures, 500, 600, and 850 °C, for ethyl methacrylate, and it became apparent that the highest temperature was too high because only small molecules remained and structural detail was lost. Pyrolysis at the lowest temperature
Figure 9 Use of Py/GC to differentiate wood species from different areas.

resulted in a few pyrolysis products that did not reveal much structural information. The more complex pyrograms were obtained from pyrolysis at 650°C; both large and small fragments were obtained that were necessary for identification. The same process was repeated on other types of polymers and, for most of them, 650°C gave good pyrograms. Library entries for polymers that do not pyrolyze well at this temperature will be done after pyrolysis at higher temperatures. The basic GC conditions required for the separation of polymers have been in use for some time. It is desirable to chromatograph to as high a temperature as possible. Temperature programming at 6°C min⁻¹ seems to be ideal for a 30-m capillary column. Faster programming results in the overlap of too many peaks, while a slower program results in very long analysis times.

The development of a Py/GC/MS library is a noble idea. The pyrolysis products of many polymers are unusual compounds that are not found in many commonly used mass spectral libraries and this makes it difficult to identify peaks even if the expected pyrolysis products are known. Creation of a library of polymer pyrolysis products by inclusion of peaks that are identified in the polymers should simplify the analysis of the polymers. However, inclusion of a select number of peaks in the library may hinder polymer identification as the library
becomes more complex. The authors do not want to include more peaks for the sake of simplifying the library. They are confident that the majority of polymers will have unique combinations of a limited number of peaks. Hence identification will not require determining the mass spectra of more than a few peaks.

The work done by Matheson et al.\(^{(35)}\) has resulted in the production of a commercial Py/GC/MS library that, at present, is limited only to systems that use Hewlett-Packard (now Agilent Technologies Inc.) mass spectrometer equipment. Development of the library was based on the premise that “the pattern of peaks in a chromatogram is more difficult to reproduce and recognize than the pattern in a mass spectrum, since the spacing along the x axis (time) is variable with column dimensions and pneumatic parameters. In addition, a reconstructed ion chromatogram consists of thousands of individual spectra, making it a very large data file, so storage of pyrograms for comparison rapidly uses disk space\(^{(36)}\). To overcome these limitations, creation of the library takes advantage of the mass spectrometer data analysis software that permits the averaging of spectra under a peak to produce a single spectrum representative of a section of the chromatogram. Since there is no limit on the amount of time that may be incorporated into the averaging, an entire pyrogram may be averaged and stored as a single spectrum, requiring only about 0.02% of the disk space needed to store the original chromatogram. The averaged spectrum for the pyrogram may be added to the library of the mass spectrometer, or a new library of pyrolyzed polymer spectra created. The computer of the mass spectrometer is used to search and match these spectra to identify unknown polymers just as it does for the mass spectra of individual compounds. The averaged mass spectra for the pyrograms becomes a simulated pyrolysis mass spectrum, independent of the chromatographic conditions. It is believed that the combination of the averaged mass spectra and the pyrogram total ion chromatogram provides a very powerful two-pronged technique for the analysis of polymeric systems, since it permits analysis of the individual peaks in the pyrogram using standard searching libraries while providing the chromatographic pattern characteristic of the polymer, and it also permits the existing computer searching techniques to be applied to the polymer as a whole.\(^{(36)}\)

A limitation of such a library is that the search capability is restricted to a polymer index in the library and users must literally carry the electronic files or hard-copy formats of the library so as to have access to it. A report by Wang\(^{(37)}\) states that the creation and maintenance of an electronic database requires certain issues to be addressed, such as inputting data from different sources, maintenance (adding, deleting, and modifying entries), access and distribution, compatibility and integration with other databases, access from different computer platforms, and the cost of the software. The report shows how a hypertext markup language (HTML) approach to creating and maintaining a Py/GC database can address these issues. HTML is a standardized language used on the Worldwide Web. It is widely used and accepted because it is simple to program and easy to understand, is very efficient in linking files and images, and is independent of computer platform (IBM-PC, Macintosh, or any type of UNIX workstation). An unlimited number of users can view the database at the same time.

The mass spectra of complex pyrograms can be interpreted with the help of expert systems. For example, expert systems have been developed for the interpretation of pyrolysis mass spectra of condensation polymers such as polyamides and polyesters.\(^{(38–40)}\) To develop the interpretation methods, the pyrolysis products were first analyzed and correlated with the degradation pathways and the structural characteristics of the polymers. An expert system was then developed to facilitate and automate the interpretation of the mass spectral characteristics. The expert system is based on rules that were empirically extracted but includes various algorithms for processing the information on the unknown mass spectra and sorting out the results of the search. The most significant information that is extracted from the unknown spectra is the repeating unit of the polymer. Determination of the repeating unit is done by using empirical algorithms and an autocorrelation algorithm.

### 4 PYROLYSIS ALKYLATION

A large number of compounds found in pulp and paper matrices contain carboxylic acid and phenolic groups. They include natural compounds such as fatty acids, resin acids, esters, soaps of fatty and resin acids, lignins, and hemicellulose adducts, and synthetic polymers such as polyesters, phenolic resins, and polymer additives. The synthetic polymers originate from the erosion of plastic equipment in the pulp and papermaking process and from the recycling of paper that contains plastics, glues, adhesives, coatings, and other polymer additives. Inadvertent introduction of plastic materials into the process, such as styrofoam cups, chewing gum, hard hats, pens, etc., is another source of synthetic polymers in pulp and paper mills. Once introduced into the process, these polymeric materials can be pulverized into small particles that affect productivity and product quality. A large number of these unwanted contaminants stick to process equipment to cause process upsets at the manufacturing site and/or at the customer site in the printing or conversion
processes. They are commonly referred to as “stickies”, owing to their tacky characteristics. Mills that supply pulps to customers who are sensitive to plastic contaminants take extra measures to minimize the introduction of plastic materials in the process. These include banning the use of plastic cups and plastic pens by mill personnel and visitors alike, and requiring that logs brought into the mill have labels/tags that are not made of plastic.

Mills that make recycled papers take extra measures to try to reduce the amount of these contaminants in the final product. These include using high-quality furnish (low in synthetic polymeric content) and installing efficient cleaning and screening unit operations. If production problems occur due to deposition or accumulation of these contaminants, it is necessary to analyze them to determine their composition and then work backwards to ascertain their origin. Analytical pyrolysis is a valuable tool in the characterization of the synthetic polymers. The diverse synthetic polymers that may be found are listed in Table 3.

Pyrolysis of these compounds yields a wide range of compounds that vary from nonpolar (e.g. alkanes and alkenes) to highly polar (e.g. alcohols and carboxylic acids). If carboxylic acids are the starting compounds they can undergo decarboxylation during pyrolysis. The polar compounds can give useful information about the structure of the polymer. Examples include the pyrolysis of polyesters to give polybasic acids and alkenes, epoxies to phenolic compounds, and polyamides to amines and carboxylic acids. The polar compounds are normally difficult to analyze by GC because they are prone to adsorption on wall surfaces in the pyrolyzer, the injection system, and the analytical column. Polar pyrolyzates often show peak-tailing characteristics, poor reproducibility, long chromatographic times, and in some cases loss of peaks. In conventional GC, these problems can be overcome by derivatizing with an alkylating reagent, such as tetramethylammonium hydroxide (TMAH), prior to analysis by GC. The derivatization can be done externally or by in situ derivatization in the injection port of a gas chromatograph. This saves time and is less likely to lead to sample loss during manipulation. These procedures, however, cannot be used for on-line Py/GC.

Instead, the pyrolysis products can be derivatized prior to GC analysis. An early example of this procedure was flash derivatization, with a butylating agent, of a copolymer of vinyl acetate, crotonic acid, and a complex vinyl ester. The reaction resulted in the formation of butyl acetate and a mixture of higher isomeric butyl esters. The polar compounds, however, cannot be used for on-line Py/GC. Analysis of these compounds by normal Py/GC does not give results that are in agreement with wet chemical methods or spectroscopic techniques because they undergo decarboxylation during pyrolysis. This problem can be overcome by pyrolytic alkylation. This technique has been studied and used in numerous applications. It has been called by a number of terminologies including reactive pyrolysis, on-line pyrolysis, thermally assisted hydrolysis, pyrolysis methylation, and simultaneous pyrolysis methylation (mainly because the most widely used alkylating agent contains methyl groups). The mechanism of

PVA, poly(vinyl acetate).
the reaction is shown in Equation (1):

\[
\begin{align*}
\text{CH}_3\text{--N--CH}_3\text{OH}^- & \xrightarrow{\text{heat}} \text{CH}_3^+ \rightarrow \text{RCOOH} \rightarrow \text{RCOOH}_2 \\
\text{TMAH} & \quad \text{Methylcarbonium ion}
\end{align*}
\]

(1)

The methylcarbonium ion will react with compounds that have reactive amino, hydroxyl, and carboxyl functional groups.

The technique has been adapted for Py/GC analysis. Pyrolysis of carboxylic acids, carboxylic acid salts, esters, polyhydric alcohols, and phenolics in the presence of an alkylating reagent such as TMAH avoids decarboxylation and degradation of the compounds resulting in their alkylation.\(^{29,47,48}\) The alkylation leads to improved chromatographic analysis of the derivatized compounds. For example, pyrolysis of polyesters involves scission of the RCOO--R bond resulting in the formation of the respective carboxylic acid and alkene.\(^{42}\) Pyrolysis with a methylating agent results in the formation of the methyl esters of the carboxylic acids and methyl ethers of the alcohol. An example of the powerful effect of the derivatization is illustrated in Figure 10(a) and (b). It is evident that pyrolysis alkylation results in a clean and sharp pyrogram owing to methylation of the pyrolyzed rosin size fragments.

Analytical pyrolysis in the presence of a methylation agent but at a lower pyrolysis temperature has been termed thermally assisted hydrolysis or methylation (THM).\(^{49}\) Analytical pyrolysis requires the absence of oxygen to avoid oxidation of the sample. The THM technique is especially sensitive to the presence of traces of oxygen because the strong alkaline medium facilitates autoxidation reactions.\(^{50}\)

A typical pyrolysis alkylation procedure entails placing 2µL of an alkylating agent such as TMAH (25% w/w aqueous solution) or tetrabutylammonium hydroxide (40% w/w aqueous solution) on the sample (~5 µg) placed in the pyrolyzer. The sample is then pyrolyzed and the pyrolysis products are analyzed by GC. Pyrolysis methylation is inappropriate for the derivatization of low-molecular-weight pyrolysis products that have very short retention times or co-elute with other pyrolysis products. For such compounds pyrolysis butylation results in the formation of butyl compounds that exhibit good chromatographic properties. The procedure has been used successfully for vinyl acetate, methacrylic acid, and cyanoacrylate homopolymers and copolymers.\(^{29}\)

Examples illustrating the use of pyrolysis alkylation in the analysis of synthetic polymers are given in section 8.

![Figure 10](image-url) Effect of in situ alkylation on the pyrolysis of rosin size.
Although pyrolysis methylation has found widespread use in various pulp and paper matrices, it has a limitation in that it is unable to distinguish between the methoxyl groups originally present in a polymer and the free hydroxyl groups that become methylated after pyrolysis. Such a distinction is needed in lignin chemistry where lignins are characterized by the ratio of phenolic groups to hydroxyl and methoxyl groups. A butylating agent does not have the limitation of its methyl counterpart. For example, Martin et al. have shown that pyrolysis in the presence of tetrabutylammonium hydroxide results in derivatization of the free hydroxyl groups present in lignin before pyrolysis (to form O-butyl ether methoxyl groups). The mechanism is thought to be thermally assisted hydrolysis followed by alkylation, and not true pyrolysis followed by in situ alkylation of the products.

A potential problem with TMAH is that it can result in the production of multiple peaks in chromatograms owing to isomerization of the compound. Another problem is that the methylation can result in the production of benzenecarboxylic acids from unoxidized lignin. Therefore, caution is required when interpreting the presence of benzenecarboxylic acids as pre-existing structural units of lignin.

Still another problem with pyrolysis methylation is that the process does not distinguish fatty acids from fatty acid esters. For example, analysis of wood extractives containing free fatty acids and glycerides of fatty acids will yield a pyrogram with peaks corresponding to methylated fatty acids with no indication of their origin: the free fatty acid will be methylated whereas the glycerides will be hydrolyzed first to release glycerol and fatty acids that will then also be methylated. A report by Hardell and Nilvebrant shows that pyrolysis using a methylating agent TMAH and an acetylating agent (tetramethylammonium acetate (TMAAc)) can distinguish free and esterified acids according to Equations (2) and (3):

\[
\text{RCOOH} + R^1\text{COOR}^2 \xrightarrow{TMAH} \text{RCOOMe} + R^1\text{COOMe} + R^2\text{OMe}
\]  
(2)

\[
\text{RCOOH} + R^1\text{COOR}^2 \xrightarrow{TMAAc} \text{RCOOMe} + R^1\text{COOR}^2 + R^1\text{COOMe}
\]  
(3)

TMAAc has less alkalinity than TMAH and consequently does not degrade esterified acids.

Figure 11(a) and (b) illustrate the selectivity of the approach: reaction of TMAH with tripalmitin yields two

![Figure 11](image_url)
peaks corresponding to methylated palmitic acid and unreacted tripalmitin. Reaction of the same compound with TMAAc yields only one peak corresponding to tripalmitin. No other peak is detected, indicating that TMAAc does not degrade the tripalmitin.

Pyrolytic alkylation is different from fusion GC or derivatization prior to Py/GC analysis. It uses the alkylation agent to hydrolyze/derivative polymers in the injection port or in the pyrolysis chamber. In fusion GC a large excess of the reagent is mixed with the polymer and the mixture is heated to above the melt temperature, resulting in hydrolysis or cleavage of the polymers and generating low-molecular weight compounds that are amenable to GC analysis. Derivatization prior to Py/GC analysis entails reaction of functional groups in the polymer prior to analysis. This requires that the polymer be stable enough to resist attack from the derivatizing agent below the temperature at which pyrolysis takes place. The technique can be used to study the degradation mechanisms of polymers. For example, the degradation mechanisms of a poly(vinylcarboxylic acid) and its alkyl ester analog were studied after derivatization of the acid by reaction with TMAH for 2 h at 100 °C in an air-cooled reflux flask.

5 APPLICATIONS OF ANALYTICAL PYROLYSIS

5.1 Analysis of Natural Polymers in Wood and Pulps

The major composition products of wood are cellulose, hemicelluloses, lignin, and extractives. The average composition of these compounds in softwood and hardwoods is illustrated in Figure 12.

Cellulose determines the character of wood fibers and enables them to be used for papermaking. It is a polysaccharide of glucose units with the formula \((\text{C}_6\text{H}_{10}\text{O}_5)_n\) where \(n\) is the number of repeating sugar units or the degree of polymerization. Decreasing the molecular weight of cellulose molecules below a certain level will cause deterioration in strength of the paper products. Hemicelluloses are polysaccharides of five different sugars from hexoses (glucose, mannose, galactose) and pentoses (xylose, arabinose). These sugars combine with uronic acids to form various polymeric structures that are associated with the cellulose portion of wood or with lignin. The hemicelluloses are susceptible to more degradation and dissolution than cellulose during chemical pulping. Lignin is an amorphous, highly polymerized substance that cements fibers together. It is a very complex polymer consisting primarily of \(p\)-hydroxyphenyl (H), guaiacyl (G), and syringyl (S) groups that are linked together in a three-dimensional structure and whose concentrations differ in softwoods and in hardwoods. In general, hardwoods contain traces of hydroxyphenyl groups, 29–35% guaiacyl groups, and 40–60% syringyl groups, whereas softwoods contain traces of hydroxyphenyl groups, \(>95\%\) guaiacyl groups, and 1% syringyl groups. Usually, lignins are classified as G, G/S or H/G/S lignin depending on the presence of the different groups. The lignin is dissolved during chemical pulping to free the cellulosic fibers. Extractives are a diverse list of compounds that are soluble in water or lipophilic solvents: they include resin acids, fatty acids, fats, terpenoids, phenols, and alcohols.

The main objective of chemical (kraft) pulping is to dissolve lignin and free the cellulosic fibers. The idea is to remove as much lignin as possible without doing too much damage to the cellulose and hemicellulose matter. It is therefore desirable to analyze for these compounds to monitor the pulping process. Traditional methods for measuring carbohydrates in kraft pulps are time-consuming; they entail acid hydrolysis, reduction to form alditols, acetylation of the alditols, and GC analysis of the acetates (see the article Pulp and Paper Matrices). The hydrolysis step can lead to erratic results because the polysaccharides in the pulps have different glycosidic linkages that do not hydrolyze at the same rate. For example, the hydrolysis of furanosides in xylans proceeds 10–1000 times faster than that of pyranosides. Lignin is measured by gravimetry after its precipitation with acid or by spectrophotometry.

Py/GC can be used for the better characterization and analysis of native polymers, as will be shown in the next few subsections.

5.1.1 Cellulose

An early study on analysis of microcrystalline cellulose with a Curie point pyrolyzer showed that furfural and levoglucosenone were the major pyrolysis products. Small amounts of 1,6-anhydro-3-deoxy-\(\beta\)-D-glucopyranose were detected. Pyrolysis of glucose and oligosaccharide standards with up to five glucose units showed that very
small amounts of the cellulose pyrolysis products were obtained. From this, two pyrolysis mechanisms were proposed.

Later, Py/GC/MS with a Curie point pyrolyzer was used to analyze microcrystalline cellulose. High-resolution MS identified 96 compounds that were classified into several groups, namely carbonyl compounds, acids and methyl esters, furans, pyrans, anhydro sugars, and hydrocarbons. Levoglucosan was the major product detected. The data enabled the authors to propose several mechanisms for the pyrolysis of the cellulose. Later work by Wada et al. using the same kind of pyrolyzer, showed that the degree of substitution of the constituent glucose unit influenced the amount of levoglucosan generated.

5.1.2 Carbohydrates

Py/GC studies of carbohydrates have shown that the method can successfully identify the saccharide composition of a wide range of heteropolysaccharides by the ability of the pyrolysis technique to produce individual anhydro sugar fragments which are further separated and identified by GC/MS. However, quantitative analysis of polysaccharides has been difficult when noncarbohydrate materials and metals are present, as is the situation with wood and pulp samples. A study by Kelly et al. showed that removing metal ions, e.g. by acid washing, overcomes the difficulty, resulting in the generation of reproducible yields of anhydro sugar products.

The technique is applicable to both mechanical and chemical pulps and the resultant pyrograms are similar to that of pure microcrystalline cellulose and a xylan polymer. The pyrograms reveal differences in the cellulose compositions of the pulps: high-yield mechanical pulps retain their original saccharide content, although some hemicellulose is lost during pulping; lower yield chemical pulps have much higher concentrations of cellulose and much lower concentrations of hemicellulose that is dissolved during cooking. Table 4 lists the identities of the pyrolysis products and shows that almost all the peaks are pyrolysis products of pentose or hexose units. This study showed that acid washing apparently reduces the concentrations of the unknown peaks.

5.1.3 Lignins

Lignins can be characterized by a number of methods that entail degradation of the compounds, the most common and simplest of which is oxidation with nitrobenzene. However, these methods, including the simplest one, are time-consuming and tedious. Py/GC is ideal for characterizing lignin groups, as has been shown by a number of researchers. For example, Faix et al. studied lignins in several wood species by Py/GC/MS and off-line Py/GC. This extensive study addressed issues such as determining the best method for wood and lignin samples, the overall yields of pyrolysis products identified by GC, the reproducibility of the pyrolysis experiments, whether or not it is necessary to isolate lignin from lignocellulosics, and compared Py/GC/MS and off-line Py/GC with other degradation methods for lignin. The pyrolysis was done with a resistively heated pyrolyzer. Four lignocellulosic samples from beech, spruce, bamboo and teak wood, and lignins isolated from the samples were used in the study. Py/GC/MS analysis allowed the assignment of 67 mass spectra to the most prominent lignin-derived degradation products, most of which were phenols containing methoxy groups and C1–C3 saturated and unsaturated alkyl substituents. Fifty of these compounds could be identified by off-line Py/GC using authentic standards. A comparison of the off-line Py/GC (with a flame ionization detector) and Py/GC/MS pyrograms is shown in Figure 13(a) and (b). A major characteristic of the on-line pyrogram is the presence of a broad peak due to levoglucosan. It is evident that there are differences in the intensities of peaks in the two pyrograms and this is related to the peculiarities of the methods used and the specific sensitivities of their detectors. Conclusions from the study were that off-line Py/GC is a suitable method for lignin classification of lignocellulosic materials with no prior isolation of the lignin; pyrolysis allows the quantitative determination of H : G : S ratios of lignins and the results are similar to those obtained by nitrobenzene oxidation.

oxidation and FTIR analyses; Py/GC/MS facilitates the interpretation of complex lignocellulosic pyrograms, for example, by excluding ions of carbohydrate-derived degradation products.

Japanese researchers used Py/GC to evaluate the uniformity of delignification of beech wood chips by monitoring residual lignin in alkali pulps. Analysis of the samples identified 10 pyrolysis products whose structures were related to vanillin, isoeugenol, syringols, and guaiacols. The calculated S:G ratio correlated with the Klason lignin contents of kraft and soda–anthraquinone beech pulps. Analysis of this ratio in samples of chip slices during a cook can be used to evaluate the uniformity of delignification.

The same researchers also used Py/GC to analyze lignin in different paper furnish including printing and writing paper, wood-containing paper, wood-free paper, and wood-containing coated paper. Their results showed that papers containing hardwood mechanical pulps could be clearly distinguished from the other papers, owing to the presence of syringyl-type pyrolysis products. An advantage of Py/GC over other traditional methods for lignin measurement such as the Klason technique is that it is not affected by the presence of fillers in the papers.
Other workers have used Py/GC to differentiate paperboards made from mechanical and biomechanical wheat-straw pulps and various proportions of wastepaper. Their results showed that yields of methoxyphenols with an oxidized n-chain correlated with wheat-straw content, whereas the yields of cinnamyl and syringyl phenolics correlated with wastepaper content. In addition, the yields of six pyrolysis products, of which anhydro sugars were the major components, correlated with the pulping method.

Py/GC/MS has been used to determine the amount of lignin present in paper mill wastewaters. The residual chemical oxygen demand (COD) in treated effluent was attributed to lignins that originated from conifers. The pyrolysis yielded guaiacol and 4-methylguaiacol fragments that were used to quantify the lignin in the effluent. The former was the best compound for the quantification.

Detection of high-molecular-weight products provides information on building blocks of lignin. However, the compounds are not volatile enough to be detected by normal Py/GC but can be detected when the pyrosis is performed in the presence of alkylating agents that increase their volatility (on-line pyrolysis alkylation). For example, Izumi et al. used the technique to characterize the lignin of more than 30 hardwood species. The major products generated were syringaldehyde and guaiacol. The data obtained were compared with those given by the traditional nitrobenzene oxidation method that yields syringaldehyde and vanillin as the major products and the results showed that there was good linear correlation between the two ($R > 0.85$). The authors concluded from this that Py/GC is applicable to the analysis of lignocellulosic materials with a wide range of syringaldehyde to guaiacol ratios.

Hardell and Nilvebrant used on-line pyrolysis methylation for the structural analysis of isolated and native lignins in wood and mechanical pulp. The samples studied were milled wood lignin (MWL) prepared from Scandinavian spruce (MWL and acetone-extracted lignin), and chemithermomechanical pulp (CTMP) bleached with hydrogen peroxide. The authors observed that normal pyrolysis resulted in low pyrosis yields of the lignins due to loss or adsorption of the pyrolysis products on the GC column. When the pyrolysis was performed at lower temperatures in the presence of a methylating agent, the dominant lignin products retained more of their structural information, and previously nonvolatile carboxylic acids were methylated and made volatile. The compounds identified using on-line pyrolysis methylation are listed in Table 5.

Pyrolysis at 360°C was sufficient for MWLs in the presence of a methylating agent. No pyrolysis products were obtained when the lignin was pyrolyzed in the absence of the methylating agent at this temperature. The pyrolysis products listed in Table 5 show that all the products were based on the expected monomeric lignin veratryl units. The main products contained side chains with methylated and carboxylic acid groups together with small amounts of keto and aldehyde groups. Fractionated pyrolysis of the lignin in the presence of the methylating agent, that is, initial pyrolysis at 360°C followed by another pyrolysis of the same sample at a higher temperature (650°C), showed that the pyrolysis products generated at the lower pyrolysis temperature accounted for 95% of the total pyrolysis products of both pyrolyses.

The results obtained by Hardell and Nilvebrant did not show any pyrolysis products that contained phenolic groups. This is contrary to literature data that showed the presence of phenolic compounds. Studies have shown that incomplete methylation is possible at times. The authors speculate that the incomplete methylation may be due to limited access of the sample to the methylating agent, or to nonintimate contact between the sample and the pyrolysis filament. They conclude that the pyrolysis of MWL in the presence of a methylating agent can be interpreted as thermally assisted hydrolysis followed by in situ methylation rather than a traditional pyrolysis. This pyrolysis technique yields fragments that are in better agreement with the accepted structure of lignins than the fragments obtained after conventional pyrolysis.

a V = veratryl (3,4-dimethoxyphenyl).
On-line pyrolysis methylation of lignin at a higher temperature does yield pyrolysis products that contain phenolic compounds. For example, data generated by Kuroda and Izumi (75) showed that pyrolysis at 500°C released high-molecular-weight compounds that were volatile enough to be detected by GC. Pyrolysis of five lignin dimer model compounds provided little information on the \( \beta\-O\-4 \) lignin building blocks. However, the technique was found to be ideal for the analysis of the \( \beta\-\beta \), \( \beta\-5 \), and \( \beta\-1 \) building blocks in lignin.

Py/GC studies on lignins seldom involve absolute quantitation of the lignin in the analyzed samples. The few that have been used are based on off-line Py/GC that entails trapping of the pyrolysis products for subsequent analysis. Obviously this methodology defeats some of the advantages of analytical pyrolysis, such as on-line analysis and minimal sample preparation. A report by Bocchini et al. (76) shows that absolute quantitation of lignin by Py/GC/MS is possible using an internal standard. Tests on linearity and reproducibility of response of several standards showed that 1,3,5-tri-tert-butylbenzene was the best. The compound vaporized in the hot pyrolysis interface during the 3-min equilibration and condensed as a plug on the GC column, thereby avoiding its loss by thermal fragmentation. Correction factors for the main lignin pyrolysis fragments were calculated and the technique was then used to analyze a wheat straw sample. The results for pyrolysis fragments of the lignin are shown in Table 6.

The data show that the most abundant compounds were phenolics, namely 4-vinylguaiacol, 4-vinylphenol, 2,6-dimethylphenol, vanillin, and 4-vinyl-2,6-dimethoxyphenol. These compounds are characteristic of the pyrolysis of lignocellulosics and are products of thermal cleavage at different sites of the phenylpropanoid structure of lignin. According to the authors, the total amount of lignin listed in Table 6 is consistent with bibliographic data obtained using classical analytical techniques such as neutral-detergent fiber analysis and Klason lignin.

Studies have shown that lignin and carbohydrates can be analyzed simultaneously in both mechanical and chemical pulps by Py/GC/MS. (15,77) The studies also showed that, for chemical pulps, there was a relatively good correlation between the sugar components (arabinose, xylose, mannose, galactose, and glucose) determined by Py/GC/MS and those obtained by traditional methods. Changes in the chemical composition of softwood pulp fibers induced by kraft pulping were monitored by measuring the amounts of lignin and carbohydrates in kraft pulps using analytical pyrolysis and multivariate data analysis, namely PCA and PLS analysis. To quantify the lignin and carbohydrates in the pulp, a multivariate calibration model was calculated by correlating the Py/GC/MS results with those obtained from the traditional acid hydrolysis/derivatization GC procedure. The ability of the calibration model to predict the lignin and carbohydrate content was studied using a number of test samples whose Klason lignin content varied from 85 to 25 and pulp yields from 59.7 to 43.1%. The lignin and the main carbohydrate components (glucose, xylose, and mannose) in the test samples could be readily predicted from Py/GC/MS analysis. For the minor sugar components (arabinose and galactose), the difference between the predicted values from Py/GC/MS and those obtained by acid hydrolysis was larger owing to the poor reproducibility of their analysis by the wet-chemical method. The reproducibility of the quantitative analysis of lignin and the five main sugars in kraft pulp was better in Py/GC/MS than in the traditional method using acid hydrolysis/derivatization GC. This was proof that improved quantification of lignin and the main sugar components can be achieved by using Py/GC/MS.

Further studies have confirmed that Py/GC/MS can be used for the simultaneous analysis of polysaccharides and lignins. For example, Kleen and Lindstrom(76) used the technique to analyze the compounds in newsprint process waters. The pyrolysis products were compared with those obtained from pyrolysis of CTMP, its isolated fractions, and the newsprint paper itself, to ascertain the characteristic features of the dissolved polysaccharides and lignins in the process waters. In addition, the lignins and polysaccharides in fines were compared with those present on the long fiber fractions. The results showed that the main compounds in the dissolved substances were galactomannan, arabinogalactan and poylarabinan that originated from hemicelluloses and pectic compounds. Only small amounts of xylan were found. Lignin or lignin-like compounds with a chemical structure different from that of the lignin in the fines were found to be closely associated with the polysaccharides dissolved in the waters. The authors conclude that the lignin in CTMP, especially the fines fraction, is enriched with coniferyl alcohol units.

Py/GC/MS studies by Hardell and Nilvebrant(50,53) have also shown that the technique can be used for simultaneous analysis of lignin and carbohydrates. Their studies on a lignocellulosic sample by THM with pyrolysis at 360°C showed that lignin fragments were the main products but small amounts of fragments derived from carbohydrates were also observed.50 Analysis by conventional analytical pyrolysis had previously led to misidentification of the carbohydrates as products derived from syringyl lignin units.79 Pyrolysis of a methoxyhydroquinone standard using the THM technique confirmed the presence of the carbohydrate, leading the authors to interpret this as evidence of the presence of carbohydrate–lignin linkages.

Analytical pyrolysis has been used to characterize chlorinated organic compounds in pulp and paper samples. For example, Van Loon and Boon80 used the techniques for qualitative analysis of chlorolignins and lignosulfonates in pulp mill effluents discharged into the Rhine river. Three different kinds of compounds were isolated from the effluents: high-molecular-weight macromolecules that were isolated by ultrafiltration and concentrated by freeze-drying; volatile compounds that were isolated by a closed-loop stripping analysis system before trapping on to carbon and desorption with carbon disulfide; and apolar and medium-polarity compounds that were isolated by adsorption on XAD-4 resins followed by desorption with dichloromethane and then concentration by evaporation to small volumes. The high-molecular-weight compounds were studied by Py/MS using a resistively heated pyrolyzer and the results showed small peaks due to guaiacyl or syringyl derivatives and intense peaks from small sulfur- or chlorine-containing products, namely H₂S, CH₃SH, CH₃SCH₃, SO₂, CS₂, CH₂Cl, and HCl. The authors explained that this was due to the highly sulfonated, chlorinated, and oxidized nature of the chlorolignins and lignosulfonates that consequently have relatively low aromatic contents and high aliphatic group contents. The guaiacyl derivatives were detected in effluents from a mill pulping softwood, whereas the syringyl derivatives were found in hardwood mill effluents. This illustrates that analysis of mill effluents by Py/MS can be used to determine the wood furnish used in the mill. Further study of the generation of SO₂ led the authors to conclude that the technique can also be used for specific quantitative determination of lignosulfonates. The high-molecular-weight material was also studied by Py/GC/MS using a Curie point pyrolyzer and the results showed that about 150 products were obtained that varied in molecular weight from 44 (carbon dioxide) to 272 (1,2-diguiacylethenelene). Chloroguaiacols, structurally very specific pyrolysis products of aromatic chlorolignins, were also observed and were proposed as chlorolignin markers for quantitative determination of chlorolignins in process waters.

Later studies by Koda et al.81 described a Py/GC/MS procedure to determine the fate of high-molecular-weight chloroorganics produced by chlorine bleaching. The compounds were extracted from chlorinated pulps with aqueous dioxane or aqueous sodium hydroxide and the extracts were then subjected to ultrafiltration (cut-off 10,000 Da) to obtain the high-molecular-weight compounds. The compounds were analyzed by Py/GC/MS, using a microfurnace pyrolyzer, and the pyrolysis products were compared with those obtained after pyrolysis of MWL and residual lignins isolated from oxygen- and ozone-bleached pulps. The data showed that the major pyrolysis products in all the samples were alkane derivatives but pyrolyzates containing aromatic structures were also present in the chlorine-bleached lignins. This is the first study showing the presence of alkanes after pyrolysis of lignins – the authors postulated that the alkanes are generated by in situ hydrogenation reaction of some common precursors during pyrolysis. The most significant difference between chlorine-oxidized lignins and other oxidized lignins was the presence of small amounts of chlorinated phenols in the chlorine-bleached lignins.

Flodin et al.82 used Py/GC and Py/GC/MS techniques to search systematically for halogenated structures in natural organic matter. Results for analytical pyrolysis with on-line methylation on aquatic fulvic acid (FA) and two samples of high-molecular-weight organic matter isolated from bleached kraft mill effluents (BKME) strongly indicated the presence of chlorinated 4-hydroxyphenyl structures in the original FA samples, whereas the BKME samples showed that the main chlorinated
pyrolysis products were guaiacyl- and syringyl-derived compounds.

5.2 Analysis of Deposits and Impurities by Normal Pyrolysis

Pulp and papermaking processes are sometimes plagued with deposition problems that cause breaks and/or off-quality products in the form of dirt and specks in the product. Such products are culled or sold at below premium prices. Rapid characterization of the deposits is essential in order to find solutions to the problems. Analytical methods have been developed to determine the composition of the deposits; they range from simple spot tests\(^{83}\) to sophisticated techniques that include solvent extraction and instrumental analysis by FTIR spectroscopy, GC, GC/MS, and scanning electron microscopy.\(^{84}\) In many instances, the concentrations of impurities in pulp and paper products are too low for analysis by solvent extraction followed by GC analysis of the extracts. FTIR spectroscopy with a diamond cell or a microscope can be used to characterize the dirt spots but it may not give definite answers on the composition of the spots. Analytical pyrolysis offers an alternative rapid technique to characterize these deposits. No (or minimal) sample preparation is required and very small amounts are required. The following examples illustrate applications of Py/GC in troubleshooting deposition problems in pulp and paper mills.

5.2.1 Deposit Sample from a Coated Paper Mill

A coated paper mill employing a mixture of groundwood and kraft pulps was experiencing deposition problems on the paper machine foil blades. The deposit was grey in color and had a rubber-like texture. Py/GC analysis of a sample (see Figure 14a and b) showed the presence of latex, styrene–butadiene copolymer, in the deposit.\(^{85}\) The copolymer is a major component in paper coating formulations. In this case, repulping of off-quality coated paper was the cause of the deposition problem. The amount of latex in the deposit was determined to be 10.3% by comparing the peak area at 7.37 min with peak areas of copolymer standards at the same retention time. The larger peak eluting at 4.90 min was not used for quantitation because its total area was not reproducible, and is probably due to other components in the latex formulation such as stabilizers, preservatives, or emulsifiers.

5.2.2 Sticky Deposit from a Fine Paper Mill

A fine paper mill had a deposit that seemed to have a texture usually associated with sticky deposits found in mills that use or make recycled papers. This was a puzzle since the mill was using virgin fiber with no recycled content. The texture of the deposit was very similar to that of chewing gum, which led to speculation that chewing gum could have been inadvertently introduced into the mill process. Py/GC analysis of the deposit sample and a sample of masticated chewing gum indicated that most of the peaks in the pyrogram of the deposit sample matched those of the chewing gum sample, as shown in Figure 15(a) and (b). Quantitation using the peaks areas at 5.65 min showed that there was 80% gum in the deposit.

5.2.3 Streaks on Tissue Paper from a Tissue Mill

A tissue paper mill experienced production problems due to plastic-like streaks that were stuck on to the paper in the dryer section of the mill. Py/GC indicated that the contaminant was due to PVA, as shown in Figure 16(a) and (b). Quantitation of the PVA in the sample showed that the sample was 100% PVA. The polymer had been introduced into the mill system with recycled paper and was melting to cause streaking in the dryer section.

5.2.4 Impurities in a Totally Chlorine-free Bleached Pulp

Py/GC/MS was one of the techniques that was used for the analysis of impurities that occurred during the
5.3 Analysis of Deposits by Pyrolysis Alkylation

Many of the compounds present in deposits and impurities contain polar groups such as carboxylic acid and alcohols. Their pyrolysis products are difficult to analyze on a GC column, but the analysis can be improved by pyrolysis alkylation of the spots. Ideally the impurities should be extracted from the fiber matrix using a pair of tweezers. Wetting the paper and observation under a stereo microscope is helpful in doing the extraction. Studies by Hardell\(^3\) showed that a resistively heated pyrolyzer can be used for the analysis of the impurities. The sample is placed in the middle of the platinum filament and \(0.5 \mu\text{L}\) of TMAH (10% w/w aqueous solution) is added to the sample using a syringe. The mixture is dried before inserting the probe into the pyrolysis chamber. The sample is pyrolyzed for 2 s at 600 °C. The pyrolysis products are analyzed by GC or GC/MS. The following are examples of this analytical technique.

### 5.3.1 Specks in Paperboard

A multilayer paperboard product was contaminated with specks that occurred between the two layers of board. The paper was wetted and the specks were removed with as few fibers as possible. Analysis by pyrolysis alkylation showed that the main products were resin acid and maleo-resin acid methyl esters.\(^3\) Fortified sizes were produced by treatment of rosin with maleic acid (or maleic anhydride) to form maleo-resin acid adducts. The presence of these compounds in the specks was therefore evidence that fortified rosin size was the cause of the dirt problem.

### 5.3.2 Cratering in “Blown Vinyl” Wallpaper

A wallpaper product, consisting of a paper sheet coated with a layer of poly(vinyl chloride), showed defects in the form of craters that measured about 1 mm. In some cases a colored spot was present underneath the crater. Analysis of material from one of the spots in the paper by normal Py/GC showed one main product, a di-ester of \(o\)-phthalic acid. Pyrolysis alkylation of the spot revealed that there was no wood resin in the spot and the single phthalate ester peak had been transformed into three peaks corresponding to partial and total alkylation of the original plasticizer.\(^3\) Figure 17(a) and (b) show pyrograms of the spot with and without alkylation.
Py/GC/MS is very useful in tracking down the origin of deposits. Deposits induced by hardwood resin will contain, among other compounds, saturated and unsaturated fatty acids, those induced by softwood resin will contain the same components plus resin acids, those from rosin size will contain only resin acids, and those from alkyl ketene dimer (AKD) will contain derivatives of saturated fatty acids. Py/GC can differentiate among these components. This is very useful for mills that sell market pulps to customers who blend the pulps with others from different suppliers. If the customers experience deposition problems, Py/GC can help in determining which pulp or process caused the deposition problem.

5.4 Analysis of Deposition Problems in Coated Papers

Coated papers are made by coating with formulations that contain latexes. If the finished product does not meet specifications, it is reslushed and added to the papermaking furnish. The use of this reslushed furnish, termed coated broke, can cause sticky deposit problems because of the latex components that contain tacky materials. Such deposition problems are called white pitch because of the latex components that contain tacky polymers in the paper that tend to be black and/or brown. The major component of latex is a tacky styrene butadiene rubber. The white pitch problems are often solved by gradual introduction of the broke into the main furnish. Knowing the amount of latex in the broke is useful in determining how much of the broke should be added. Py/GC has been used to determine the amount of latex in coated broke. Py/GC of a commercial latex sample showed that the main pyrolysis products were butylene, methylmethacrylic acid, and styrene. Quantitation of latex in the broke was calculated based on the peak intensity of the styrene peak. Analysis of a mill sample showed that 68% of the latex was in the fines fraction of the broke, 28% was in the coarse fiber fraction, and 3% was associated with dissolved and colloidal substances.

5.5 Analysis of Rosin Sizing Agents

The sizing of paper entails attaching or anchoring of sizing agents on to cellulosic fibers. Determination of the amount of size present on sized papers is difficult to do by solvent extraction because the solvents do not remove the bound sizes. Py/GC with on-line methylation using TMAH has been used to measure rosin sizing agents in paper. The pyrolysis products, methyl esters of the rosin adducts, were used to measure the rosin size. The rosins retained in the paper were determined with a standard deviation of about 1%.

5.6 Analysis of Alkyl Ketene Dimer and Alkenyl Succinic Anhydride Sizing Agents

AKD and alkenyl succinic anhydride (ASA) are neutral sizes added to paper and board to impart hydrophobicity. These sizes are considered to be reactive sizes that react with cellulose fibers thereby imparting the hydrophobicity. Because these sizes can hydrolyze during storage or in the papermaking process before they react with fibers, it is important to ascertain how much of the compounds are present in sized sheets in order to optimize the sizing process. It is also important to measure the hydrolyzed components as they are sticky and can cause production problems. Methods have been developed for measuring these sizes in paper and deposit samples, but they are long and complex.

Py/GC offers an alternative and rapid method for the direct measurement of the sizes in paper samples. A report by Yano et al. showed that Py/GC could be used to identify AKD and ASA and the former was shown to correlate with the hydrophobicity of the paper. Vrbanac and Dixon also used the technique for quantitative analysis of the sizes in papers. Resistively heated pyrolyzers connected to a GC or GC/MS system were used. Figure 18(a) and (b) show that the pyrogram of an AKD standard matches very well that of a paper sample sized with AKD. Pyrolysis of AKD yields three main peaks corresponding to 12/14, 14/14, and 14/16 carbon side-chain lengths on the AKD. Natural polymers in the paper do not interfere because they elute much earlier than the AKD peaks. By spiking known amounts of AKD in toluene on to unsized paper, a linear calibration plot was developed using areas of the three main peaks. The calibration was used to show that the amount of size in the paper was 6.82 lb t⁻¹. However, a
Figure 18 Analysis of AKD sizing agent by Py/GC.

benchmark of three commercial liquid packaging board samples showed that AKD content as measured by Py/GC does not necessarily correlate with the off-machine sizing test that is used to evaluate the sizing or hydrophobicity of the sized papers. While the sizing tests showed significant differences between the three samples, the AKD contents of two of the papers were not statistically different.

Pyrolysis of ASA (structure shown in Figure 19a) results in a complex pyrogram as shown in Figure 20. The pattern of the pyrogram is the same irrespective of whether or not pyrolysis alkylation is performed. This complexity indicates that ASA has a large number of homologs or there is chain breakage during pyrolysis, yielding numerous pyrolysis products. A mass spectral library search of the pyrolysis products on a resistively heated pyroprobe linked to a GC column and an ion trap quadrupole mass spectrometer shows octadecenyl-succinic acid, dodecen-1-yl-(−)-succinic anhydride and a pentamethylheptadecatetraenecarboxylic acid as some of the major degradation products.\(^94\) Data from Vrbanac and Dixon\(^93\) show that the pyrolysis calibration curve for ASA is not linear but can still be used to calculate the amount of size in paper. Analysis of ASA products from different suppliers shows that they have different pyrograms as shown in Figure 21(a–c). Each ASA has a different peak pattern, confirming that the isomeric olefin stocks for making ASA are different. These peak patterns can be used for qualitative identification of the sizes. An unfortunate aspect of Py/GC of ASA is that hydrolyzed ASA cannot be distinguished from unhydrolyzed ASA because their pyrograms are similar. This means that the
technique measures total ASA in the sheet with no indication of the amount of ASA that has reacted to impart sizing on fibers. Indeed, the use of Py/GC to diagnose the cause of poor sizing on a commercial paper production revealed that ASA content does not correlate with the hydrophobicity of the paper. Analysis of a paper with normal hydrophobicity and another with low hydrophobicity showed that the problem paper contained 26% more ASA than the normal paper. The cause of the lower hydrophobicity was thought to be either hydrolysis of the ASA or poor distribution and orientation of ASA on the fibers.\textsuperscript{(93)}

Py/GC has been used to study the sizing mechanism of AKD.\textsuperscript{(95)} Results from the study showed that the addition of a cationic polymer to the pulp suspension was effective at promoting sizing and there was a good correlation between the amount of AKD in the paper and its degree of hydrophobicity.

### 5.7 Analysis of Wet-strength Resin

Ascertaining the structure and mechanism of polyamide–epichlorohydrin (PAE) resins for use as wet-strength additives in paper is important but is difficult to do reliably because the additives are present in papers in very small amounts. Py/GC has been used to measure reliably the compounds in paper. Cyclopentanone derived...
from the adipic acid component of PAE was the key product for measuring the polymer in paper. Analyses were reported to be reproducible within a 4.8% relative standard deviation.\(^{(86)}\)

### 5.8 Analysis of Sulfur Compounds

Although the kraft pulping process that entails cooking wood chips in sulfide liquors is the dominant technology in the pulp and paper industry, very little is known about the fate of the sulfur component in the process (e.g., the chemical nature of sulfur in lignocellulosics). This is probably due to a lack of suitable analytical techniques for sulfur compounds. The analysis of sulfur compounds can be problematic. For example, analysis of polysulfide is hampered by the rapid deterioration of the sulfur in the samples to be analyzed. A new method for characterization of sulfur in wood and chemical pulps has been developed that employs fractionated pyrolysis.\(^{(97)}\) In fractionated pyrolysis, a sample is heated at progressively increasing temperatures for different times to enable study of pyrolysis products of the sample at the different temperatures. The influence of different pyrolysis conditions and sample size was studied on sulfur-treated wood residues and sulfur-containing model compounds. The pyrolysis was performed using a resistively heated pyrolyzer linked to a gas chromatograph with a flame photometric detector. The fractionated pyrolysis was conducted in two ways. The first was sequential pyrolysis as follows: three times at 300°C, three times at 400°C, twice at 600°C, and once at 1350°C, each time using a pyrolysis time of 2 s. The second was pyrolysis

once at each temperature for 2 s. The main pyrolysis products that were identified were \( \text{H}_2\text{S}, \text{COS}, \text{SO}_2, \text{CH}_3\text{SH}, \text{and CS}_2 \), that is, they were inorganic except for methanethiol (\( \text{CH}_3\text{SH} \)). The study seems to indicate that the majority of the sulfur in wood is inorganic, and is not associated with wood protein as had been reported previously.\(^{(98)}\)

5.9 Analysis of Ink

Printing inks are difficult to analyze because they are complex formulations of solid, volatile, and semi-volatile materials such as pigments, petroleum resins, waxes, and oils. Analytical pyrolysis may be used to characterize the solid components but the presence of volatile materials may interfere. Figure 22(a–c) show pyrograms obtained from analysis of black ink on paper, the ink by itself, and volatile components present in the ink formulation.\(^{(99)}\) The pyrograms show that both volatile and non-volatile components of the ink are present in the ink on the paper sample.

Wampler and Levy\(^{(99)}\) developed a two-step procedure to simplify the analysis of ink formulations as illustrated in Figure 23(a–c). Figure 23(a) shows analysis of an ink formulation by Py/GC. It is evident that the pyrogram is complex and has a mass of unresolved peaks that elute between 20 and 26 min. If the sample is first heated at 250 °C for 5 min in the probe of a resistively heated pyrolyzer, volatile hydrocarbon oils, which make up a large portion of the ink, are removed, leaving behind solid resins and waxes. The removed volatiles can then be chromatographed to give a pyrogram as shown in Figure 23(b). This pyrogram is akin to dynamic headspace analysis of the ink.

Pyrolysis of the remaining solids at 700 °C for 10 s and chromatography of the pyrolysis products result in a pyrogram, shown in Figure 23(c), that has near baseline separation of major peaks and also has specific peaks that may be identified and associated with individual solid constituents of the ink formulation. For example, peaks eluting between 12 and 19 min are due to hydrocarbon resins, whereas those eluting between 20 and 25 min are due to normal alkanes and alkenes degraded from the wax.

5.10 Analysis of Photocopier Toners

Analytical pyrolysis has also been used to characterize toner materials from photocopiers. Toners consist of a colorant such as carbon black or iron oxide embedded in an organic polymeric matrix. The polymer formulations used vary from one photocopier manufacturer to another and these may be easily differentiated using Py/GC and Py/GC/MS.\(^{(100)}\) Analysis of nine photocopy samples representing four manufacturers revealed that, within a manufacturer, there was little difference seen in the toner formulations used for different models. The pyrograms ranged from complex to relatively simple, as illustrated in Figure 24(a–f). Identification of the major peaks indicate that materials used in the photocopiering process include methyl methacrylate, toluene, glycidol, furfural, styrene, butyl methacrylate, dodecyl methacrylate and tetradecyl methacrylate.

Photocopier toners have also been characterized by Py/FTIR spectroscopy. The colorant materials that absorb IR radiation remain when the sample is pyrolyzed.
The volatilized products are easily detected by FTIR spectroscopy. For example, analysis of toners from three manufacturers shows that, although they are all based on polystyrene, the FTIR spectra of their pyrolysis products are different. As can be seen in Figure 25(a–c), the three toners can be easily distinguished based on the ratios of the absorbance at absorption bands that match the pattern formed by styrene (major peaks at 774 and 910 cm\(^{-1}\)) and those of butyl methacrylate (major peak at 1165 cm\(^{-1}\)).

6 PRETREATMENT OF SAMPLES BEFORE ANALYTICAL PYROLYSIS

The pretreatment of samples before analysis can affect the resulting chromatograms and can lead to the incorrect identification of the analyzed polymers. For example, pyrolysis of PVA samples yields different pyrogram patterns depending on whether or not the PVA emulsion was dried at high temperature before analysis. The pyrograms shown in Figure 26 illustrate this. In this case a match with the deposit sample was obtained after the emulsion had been dried before pyrolysis. This implies that standards should be subjected to temperatures similar to those experienced by the contaminants in the deposit samples in order to obtain meaningful chromatographic patterns in the pyrograms.

7 SLOW PYROLYSIS OF WOOD SAMPLES

As mentioned in the Introduction, analytical pyrolysis is normally done under rapid heating conditions to prevent condensation of the pyrolysis products. We have seen that such pyrolysis can induce reproducible degradation of wood extractives, lignins, and carbohydrate-type compounds. In many cases the degradation patterns can be used to fingerprint the parent compounds. It is interesting, however, to see how slow pyrolysis affects the degradation of lignocellulosic materials. A completely different kind of behavior is observed. For example, DeGroot et al. studied slow pyrolysis products of wood. The wood was heated at 250°C on a thermal balance and the evolved products were monitored by FTIR spectroscopy, which showed that about 60% of the weight loss was due to the formation of water, carbon dioxide, methanol, acetic acid, and formic acid. The heated wood was analyzed for glycoses and uronic acids and the data led the authors to determine the events that occur when wood is pyrolyzed. They found that the first chemical events that occur in the pyrolysis of wood include ready decomposition of uronic acids in the hemicelluloses and pectic substances to form carbon dioxide, water, char (or char precursors), and some methanol. The decomposition may lead to further pyrolysis of the xylose units to which the uronic acids are attached in the hemicelluloses. Acetyl ester groups in the hemicelluloses are much more resistant to pyrolysis, but are released slowly as acetic acid. Formic acid
is released at a slow but steady rate by unknown mechanisms and is probably derived from degradation of hemicellulose.

A report by Ingemarsson et al.\(^{102}\) discusses slow pyrolysis of wood samples from several species of European spruce and pine trees. The samples were subjected to slow pyrolysis in a reactor and the products analyzed by GC/MS, GC/FTIR/FID, and by trapping on solid-phase extraction cartridges for later analysis by GC/MS. A schematic of the pyrolyzer, a variant of a furnace pyrolyzer, is shown in Figure 27. The pyrolyzer can be heated up to 900 °C but in this case it was maintained at 550 °C with a nitrogen gas flow rate of 40 mL min\(^{-1}\).

It is interesting to note, from the data, that the pyrolysis of pine and spruce samples produced substantial amounts of carbon monoxide and carbon dioxide even though the pyrolysis was done in the absence of oxygen. Also, substantial amounts of gaseous oxygenated compounds were produced, such as methanol, acetaldehyde, acrolein, propanal, acetone, acetic acid, butyric acid, ethyl formate, and phenol. The nongaseous compounds detected by

![Schematic of a pyrolyzer for conducting slow pyrolysis studies.](image)

**Figure 27** Schematic of a pyrolyzer for conducting slow pyrolysis studies.

GC/MS for the different wood species studied are shown in Table 7.

The data show that the emissions of organic compounds from pyrolysis of spruce and pine wood samples are very complex but there are significant differences between spruce and pine species. Unfortunately, the patterns of

the pyrolysis products cannot be used to fingerprint the species. The authors conclude that the emission of large amounts of toxic aldehydes and ketones illustrate that incomplete combustion of wood biomass can lead to environmental health problems.

8 SIMULTANEOUS PYROLYSIS ALKYLATION OF SYNTHETIC POLYMERS

The following are examples of how the analysis of synthetic polymers can be characterized by analytical pyrolysis using simultaneous alkylation procedures. This information is useful in understanding the sources of contaminants and deposit problems that occur in mills that make and/or use recycled paper furnish.

8.1 Alkyd Resins

Alkyd resins are made from polyfunctional acids, polyhydric alcohols, and long-chain fatty acids from vegetable oils. Conventional Py/GC/MS of the compounds shows aldehydes, alkanes, alkenes, and phthalic anhydride. These compounds only reflect the composition of the polymer indirectly because the aldehydes, alkenes, and alkanes are low-molecular-weight fragments that have little structural similarity to the long-chain fatty acids and polyols. Pyrolysis alkylation, however, results in hydrolysis and methylation of the polar components, yielding methyl esters of the polybasic acid and long-chain fatty acids and methyl ethers of the polyhydric alcohol as shown in Figure 28(a) and (b).

Figure 28 Pyrolysis alkylation of an alkyd resin polymer. (Reproduced from ref. 29, with permission from Elsevier Science.)

8.2 Unsaturated Polyester Resins

Styrene unsaturated polyester resins are produced by esterification of o- or isophthalic acids, maleic anhydride, and polyhydric alcohols (propylene glycol and neopentyl glycol), and can be coreacted with modifying agents such as adipic acid. The styrene is added in the formulation to facilitate cross-linking.

The main products of conventional pyrolysis of one such polymer, a diethylene glycol–isophthalic–adipic acid-modified polyester, include toluene, styrene, styrene oligomers, and cyclopentanone. Pyrolysis methylation of the same polymer gives dimethyl isophthalate, methyl ethers of diethylene glycol, dimethyl adipate, and methyl benzoate (Figure 29a and b). The polybasic acid in the polymer is indicated by the dimethyl phthalate isomer, DMOP.
the polyol by the corresponding methyl ethers, and the adipic acid by its dimethyl ester.²⁹

8.3 Polyester Fibers

Polyester fibers are made mainly from poly(ethylene terephthalate) (PET) and used for making fabrics used in pulp and papermaking processes. Sugimura and Tsuge ⁴² have shown that their main conventional pyrolysis products include benzene, benzoic acid, and biphenyl. Pyrolysis methylation causes esterification of the terephthalic acid to dimethyl terephthalate and benzoic acid to methyl benzoate. Figure 30(a) and (b) illustrate the enhanced sensitivity of the methylation procedure. It is evident that pyrolysis methylation of a 1-mm fiber yields much sharper pyrograms than conventional pyrolysis of a 40-mm length of fiber.

8.4 Phenolic Polymers

Phenolic polymers that are commonly found include epoxy, polycarbonate, and phenol–formaldehyde resins. Conventional pyrolysis of epoxy resins derived from phenol A and epichlorohydrin results in mainly substituted phenolic compounds,⁴³ those from polycarbonates produce similar phenolic products and diphenyl carbonate,¹⁰³ whereas phenol–formaldehyde resin yields substituted phenols whose structure is dependent on the macromolecular structure of the resin.¹⁰⁴ Pyrolysis methylation results in the formation of methyl ethers of phenol and substituted phenolic products and gives more detailed information on the composition of the polymers, as illustrated in Figure 31(a) and (b) for an epoxy resin.²⁹

8.5 Poly(vinyl acetate)

Vinyl acetate is usually copolymerized with other vinyl monomers to make surface coatings and adhesives. Conventional pyrolysis of PVA forms aromatic compounds and acetic acid and the latter is used as a diagnostic marker for the presence of vinyl acetate in the polymer. However, the polar nature of acetic acid results in very poor chromatography of the compound. Pyrolysis alkylation with a butylating agent improves the chromatography and sensitivity of polymers that contain vinyl acetate. A typical pyrogram for a PVA adhesive pyrolyzed in the presence of TBAH is shown in Figure 32(a–c). A disadvantage of pyrolysis butylation with TBAH is the presence of by-products, n-butanol and tributylamine,
in the pyrogram.\textsuperscript{(29)} Fortunately, the compounds generally do not interfere with the interpretation of the pyrogram.

8.6 Methacrylic Acid Copolymers

Methacrylic acid is copolymerized with acrylic acid in high-quality coatings and adhesives. The acid, produced in conventional pyrolysis of this copolymer, exhibits poor chromatographic properties that are significantly improved by pyrolysis butylation of the polymer due to the formation of butyl methacrylate.\textsuperscript{(29)} The formation of the methacrylate confirms the presence of the acid in the polymer, as illustrated in Figure 33.

8.7 Cellulose Acetate Butyrate

Pyrolysis products of cellulose acetate butyrate, a flow-promoter additive in acrylic lacquer formulations, are not detected by conventional Py/GC. However, pyrolysis butylation results in the detection of butyl esters of acetic and butyric acids, as shown in Figure 34.\textsuperscript{(29)}

8.8 Polycyanoacrylates

Polycyanoacrylates are used to make high-performance adhesives. Their pyrolysis products are polar and therefore difficult to separate by chromatography.
Pyrolysis butylation yields a number of compounds, the major one being butyl cyanoacrylate (Figure 35).

X-ray photoelectron spectroscopy (XPS) also popularly known as electron spectroscopy for chemical analysis (ESCA) involves the irradiation of a solid surface in ultrahigh vacuum with monoenergetic soft X-rays. The X-rays cause electrons of an atom to be ejected and to be ionized as photoelectrons. The number of electrons and their kinetic energies are then measured. The energy of the emitted electron is very characteristic of the atom from which the electron originated and its environment. The XPS spectrum is a plot of the number of emitted electrons per energy interval versus their binding energies. Quantitation can be achieved either by fundamental parameter calculation or comparison with appropriate standards. In the pulp and paper industry, XPS has successfully been used to study migration of binder in coated paper, the surface chemistry of pulps and its effect on the properties of the final products; the adhesion between paper and polymer, toner or ink; and the chemical additives on the paper surface.

As with most analytical instrumentation, XPS has its limitations and disadvantages and is often used in conjunction with other, complementary techniques such as SIMS (secondary ion mass spectrometry) and FTIR (Fourier transform infrared) spectroscopy for the identification of organic compounds on paper surfaces. XPS is surface sensitive which renders it useless if the underlying cause of the problem might be other than surface related. XPS provides only semiquantitative information. A more precise quantification of the elements is possible, but requires exhaustive calibration.

1 INTRODUCTION

The surface composition and the surface chemistry of uncoated and coated papers strongly affect their performance. Since paper frequently is used for some form of printing application, the paper surface and its interaction with the printing medium (inks) become very critical for good print quality. With the advent of new and ever changing printing technologies, great demand is placed on paper manufacturers to change the commodity paper technologies to meet the challenges of new paper end-user requirements. The ability of the paper manufacturer to come up with paper substrates to accommodate new printing technologies expanded the markets for both print providers and paper vendors. For example, paper is now marketed which was specifically developed for ink jet printers, laser printers and color copiers. The surface chemistry and surface energetics of the papers play a vital role in the development of new paper grades and optimizing the paper performance.

A number of analytical techniques are now available to provide surface chemistry and surface compositional information without significant interference from the bulk of the sample. XPS, also known as ESCA, is ideally suited to study the paper surfaces. Although the name XPS is scientifically more correct, the commonly used name is ESCA, the title given by Siegbahn who developed this technique in 1967. Since then, several commercial XPS instruments have been developed. XPS, which has now matured into one of the most powerful and valuable methods for surface analysis, gained its distinction due to:

1. ease of interpretation of the data;
2. ability to detect all elements (except hydrogen);
3. wealth of chemical bonding information and;
4. its application to a large number of areas including, organics, semiconductors, fibers, films, powders, metals and biomaterials.

The application of this technique for the analysis of cellulosic materials was pioneered by Dorris and
2 X-RAY PHOTOELECTRON SPECTROSCOPY

XPS method is based on Einstein’s classic photoelectric effect. When a clean solid surface is bombarded by X-ray photons it emits electrons. The emitted electron, before leaving the surface, has to overcome the binding energy (BE) of the orbital in which it was located in the atom. The amount of remaining incident radiation energy results in the velocity of the ejected electron, that is its kinetic energy (KE). From the energy of the incident radiation and the KE one can calculate the BE of the electron. The BE identifies the elements present and the oxidation state of that element. The energy of the emitted electron, which is characteristic of the atom from which the electron originated and its environment, is measured by a hemispherical electron analyzer in most commercial XPS instruments. The KE of an electron leaving the solid surface is given by Equation (1):

\[ \text{KE} = \hbar v - \text{BE} - \phi_s \]  

(1)

where \( \hbar v \) = energy of the photon, \( \phi_s \) = spectrometer work function.

Since the mean free path of the electrons is very small, only the electrons that are generated from the top few atomic layers of the surface can reach the detector. Hence XPS is deemed as a surface sensitive technique. The most commonly used X-ray sources are Mg K\( \alpha \), Al K\( \alpha \), and monochromatic Al K\( \alpha \). The monochromatic source is normally used for delicate organic surfaces including paper for which high energy resolution and minimal sample damage are necessary. The disadvantage of a monochromatic source is charge buildup on the sample surface. This is generally not a major problem with nonmonochromatic sources because white radiation neutralizes the charge on the sample surface.

2.1 Surface Charging of Paper Samples

For electrically insulating samples such as papers and polymers, a positive charge on the sample surface will build up as photoelectrons are ejected. Without a method for charge neutralization, photoelectron peaks tend to change their shape and shift to higher binding energies, sometimes by as much as several hundred electron volts (eV). The current standard method for neutralization is a source of low energy electrons, usually an electron flood gun. Even with good charge neutralization, minor shifting of peaks could occur and the spectrum should be corrected for charging. It is ordinarily done by choosing a peak for which the correct BE is known. The entire spectrum is then shifted so that the reference peak is in the correct position. In the case of paper or polymer samples, the hydrocarbon component of the C (1s) line at 285.00 eV is used as a reference line. If the sample is heterogeneous (as is the case with paper) particles of different materials can charge to different extents. This phenomenon, known as differential charging, makes the interpretation of the spectrum more complicated.

2.2 Quantitative Analysis

A rigorous treatment of the theory underlying quantitative XPS analysis is beyond the scope of this article. In practice, the peak areas for the elements are converted into fractional atomic concentrations using the relative atomic sensitivity factors as shown in Equation (2):

\[ C_a = \frac{I_a/S_a}{\sum_n I_n/S_n} \]  

(2)

where \( C_a \) = fractional atomic concentration of element \( a \), \( I_a \) = peak intensity, \( S_a \) = relative atomic sensitivity factor, and the sum is performed over all elements detected in the sample.

Because of the fairly crude assumptions, the concentrations measured using this approach are probably associated with an error of about 10%. Values of \( S_n \) may be calculated from theory or derived empirically by recording spectra from standard materials. XPS instruments are generally provided with the atomic sensitivity factors and appropriate algorithms as a part of a software package for calculating the concentrations.
2.3 Depth Profile

The maximum sampling depth obtainable, even under optimum conditions, is only about 10 nm which corresponds to about 16 carbohydrate chain layers, because the thickness of a single glucose unit is approximately 0.6 nm. In most cases, the information about the surface composition within this analysis depth is extremely valuable and further analysis may not be necessary. However, XPS can also be used to investigate the variation of the composition with depth into the sample thereby producing a composition–depth profile of the surface of interest. The inert gas ion bombardment sputtering method is ordinarily used to remove sample surface beyond 10 nm. But for a composition–depth profile, in the range 1–10 nm, the angle-dependent technique is normally adapted. This is accomplished by selecting a narrow acceptance angle and varying the take off angle.

2.4 Sample Handling

For the majority of XPS applications, sample preparation and mounting are not difficult. The paper (or other samples) is used as received. The samples are mounted or mechanically held to the sample stage which is then introduced into the chamber for analysis after initial pump down. For pulp samples, laboratory hand sheets are usually made without any additives. But for characteristic bulk composition analysis, pulp or other samples are ground to powder which can be introduced by one of several methods: carefully dusting the powder on a adhesive tape, pressing powder into an indium foil, or pressing the powder into pellets. Since the XPS instrument is surface sensitive, extreme protection must be taken to avoid any contamination of the sample during and after the sample preparation.

2.5 X-ray Photoelectron Spectroscopy Spectrum

For a typical ESCA investigation, a broad scan survey spectrum (low resolution) is usually obtained first, especially if the sample is an unknown. Once the elements are identified from the survey spectrum, detailed (high resolution) scans of selected elements of interest can be obtained for chemical state identification and quantitative analysis. Survey scans ordinarily range from 1000 to 0 eV BE which is sufficient for the identification of detectable elements. A higher range of 1100–0 eV is recommended for paper samples containing Na or Mg because the strongest peaks for these elements occur above 1000 eV.

Typically the survey scans are obtained at high-pass energies and for short periods of time. The high resolution scans, on the other hand, are obtained using a narrow BE range, low-pass energy and for longer periods of time. Quantitative analysis and deconvolution manipulations of the data are done on the high-resolution spectra. The survey spectrum is displayed as a plot of BE versus intensity (counts per second per unit energy interval). Several peaks are observed in ESCA spectra but the most intense peaks are photoelectron lines. Other peaks often observed are: Auger lines, shake-up lines, valence band lines and so on which are not discussed here.

In general, interpretation of the ESCA spectrum is most readily accomplished by first identifying the lines that are almost always present, specifically those of carbon and oxygen, then identifying the other major and minor lines. Most instrument manufacturers have software programs to identify the peaks using the BE of each peak. Also, standard BE tables are available in many standard text books for manual identification of the peaks. An ESCA survey spectrum of a coated paper is shown in Figure 1. From this spectrum it can be inferred that the coating consisted of clay (Al and Si) and calcium carbonate (Ca) as pigments and probably a latex binder.

2.6 Carbon Chemistry

XPS spectra not only characterize the elements present on a surface but also provide the chemical bonding information for the elements. It has been observed that the energy of the electrons emitted from a given element may be altered (or shifted) depending on the type of chemical bond formed by the element in question. The magnitude of this chemical shift indicates the types of chemical bond present on the surface. For example, the energy of the electrons originating from carbon bonded to other carbons (C–C, 285.0 eV) is different from the energy of the electrons originating from carbon bonded to oxygen (C–O, 286.5 eV or C=O, 288.5 eV). Binding energies and chemical shifts for carbon (1s) and other atoms in organic compounds have been measured and are available in the literature.

Dorris and Gray showed from high-resolution ESCA data for mechanically refined softwood pulp that the carbon (1s) spectra consisted of three overlapping but distinctly different peaks. Based on the binding energies reported in the literature for carbon–oxygen bonds, they attributed the low-BE peak (C1) to lignin, (C–C bonds); the middle peak (C2) to cellulose (C–OH bonds); and the high-BE peak (C3) to cellulose (O–C–O bonds) where two oxygen atoms are bonded to carbon at the reducing end. Simple deconvolution methods, normally provided by the instrument software, are used to estimate the relative abundance of each class of carbon atom. The C4 carbon atoms, representing carbon bonded to a carbonyl and noncarbonyl oxygen atoms (O–C=O) are...
generally difficult to detect owing to low concentrations of carboxylic acid groups present on the fiber surface. The C4 peak, in the case of coated papers where the concentrations are greater, is clearly seen corresponding to carbon bonded to three oxygen atoms as in calcium carbonate which is used as a pigment in coating formulations.

Because carbon and oxygen are the primary constituents of paper, the BE shifts for these two elements are shown in Table 1. It should be noted that the observed chemical shifts and the absolute binding energies of the elements to some extent depend on the instrument, surface neutralization efficiency, sample type and surface roughness.

Surface damage of cellulosic materials can occur as result of exposure to high-energy X-ray radiation which might cause some physical and chemical changes without changing their appearance. Ahmed et al. studied the chemical degradation of Whatman filter paper when exposed to a high-energy X-ray source. With increasing exposure time, the O/C ratio and C2 component decreased, while the C1 and C3 components increased. They explained the results by a double dehydroxylation mechanism in which the cellulose was converted into an enone. Chemical changes of the cellulose surface structure have also been reported by Carlsson and Strom. The effect of these chemical changes should be taken into account in the analysis of ESCA data.

### 3 APPLICATIONS

#### 3.1 Pulp Characterization

The surface chemical composition of paper-grade fibers has great influence on fiber–fiber bonding, fiber–paper additive interactions, and ultimately on the final properties of the paper. The fibers undergo complex changes

CTMP, chemithermomechanical pulp; CMP, chemimechanical pulp; BCTMP, bleached chemithermomechanical pulp.

All XPS spectra and results presented in this article were generated by the author on the Perkin-Elmer PHI-5500 Multi-Technique System at Champion International Corporation in West Nyack, NY. All experiments were performed using monochromatic aluminum X-rays (Ka = 1486.7 eV) at 400 W (15 keV). The survey spectra were acquired at a pass energy of 93.9 eV whereas the multiplex spectra were acquired at a pass energy of 58.7 eV. The analysis area was about 800 µm in diameter. High-resolution carbon spectra were obtained at pass energies of either 58.7 eV or 5.87 eV. Curve fitting and quantitation were performed using routines provided by the PHI instrument software. In all cases the experiments were performed on three different sample locations and an average was calculated.

during the pulp manufacturing process, creating new fiber surfaces at each stage of pulping, bleaching, drying, and any other chemical treatment. Here, a few examples of how XPS has been used to characterize fiber surface at different stages of the pulp manufacturing process are discussed. The XPS survey spectrum of pulps shows only peaks due to oxygen and carbon and perhaps chlorine from the bleaching chemical. But the high-resolution carbon spectra and oxygen-to-carbon ratios of pulps reveal a great deal information regarding their surface structure.

Dorris and Gray\(^1,2\) studied the surface chemical composition of three mechanical pulps (stone ground, refiner mechanical and thermomechanical pulps) by XPS and showed that these fibers were distinctly different from one another with respect to the oxygen–carbon ratio and much different from the cotton fibers or the filter paper. From the molecular formula for pure cellulose, \(\text{C}_6\text{H}_{10}\text{O}_5\), the theoretical O/C ratio can be calculated to be 0.83 (five oxygens/six carbons). Almost all pulp fibers exhibit ratios much less than 0.83 due to the presence of carbon-rich lignin and or other extractives on the surface of the fibers. Practically it is difficult, in the manufacturing process, to remove the lignin completely without severely damaging the fiber surface. Lignin, a large complex molecule, exhibited a O/C ratio of about 0.3. In most cases, the O/C ratio of fibers falls between 0.83 and 0.3.

Extractive components, such as abietic acid which has an O/C ratio of 0.1, also reduce the O/C ratio of pulps. A list of O/C ratios for various pulps is shown in Table 2. The purpose of this table is only to demonstrate the differences in the surface chemical composition of various pulps. The actual concentrations of these components in a given situation might vary significantly depending upon the instrument, extent of bleaching, contamination, etc.

High-resolution carbon spectra of pulps have also been used to characterize the pulp surfaces. Theoretically, there is 0% C1, 83% C2 and 17% C3 for pure cellulose; that is all the carbons in cellulose are linked to at least one oxygen. In practice, some of the C1 on fiber surfaces is always seen due to the presence of oxygen and carbon and perhaps chlorine from the bleaching chemical. But the high-resolution carbon spectra and oxygen-to-carbon ratios of pulps reveal a great deal information regarding their surface structure.

High-resolution carbon spectra for bleached kraft hardwood and unbleached groundwood pulps are shown in Figure 2. High levels of C1 in groundwood pulp is a strong indication of high levels of lignin and other extractives compared with bleached hardwood pulp. Very little attention is usually paid to the oxygen spectra of cellulose fibers because of its complex shift behavior compared to C (1s). The complexity arises from the electronegativity and polarizability of substituent groups interacting directly or indirectly with oxygen. However,
the works of Koubaa et al., Kamdem et al., and Hua et al. shed some light on the shift behavior of oxygen in cellulose fibers. The general classification of oxygen peak components is shown in Table 1.

The effect of a steam explosion pulping process on fiber composition was examined by Hua et al. The explosion pulps showed higher O/C ratios than CMP and CTMP, indicating that the explosion pulping process had removed more extractives and lignin from the fiber surfaces. Because this facilitates hydrogen bonding between fibers, the paper made from explosion pulps provides much greater strength than the paper made from conventional pulps.

The effect of digestion parameters on the surface chemical composition of fibers was investigated by Laine et al. using XPS. A series of unbleached pulp samples were prepared by digestion in the presence of three different levels of effective alkali such that the kappa numbers are in the range 18–57. The kappa number is the volume (in milliliters) of 0.1 N KMnO₄ consumed by 1 g of moisture free pulp in 0.5 N sulfuric acid after a 10-min reaction time at 25°C under conditions such that one-half of the permanganate remains unreacted. The 50% residual permanganate is titrated to determine the exact consumption. The kappa number test is used to monitor the degree of cook (extent of delignification during pulping) and to control the process between bleaching stages. Bleached pulps always exhibit low kappa numbers and unbleached pulps give high numbers. From the XPS data for these and organic-solvent-extracted pulps Laine et al. concluded that:
and untreated birch kraft pulps has shown that the concentration of extractives was reduced when treated with xylanase as compared with treatment with mannanase, indicating that the extractives are preferentially associated with xylan. While there was no effect on surface lignin content with birch pulps, the lignin content increased in enzyme-treated pine pulp. They suggested that the lignin preferentially located under xylan which, when removed by enzyme treatment, exposed lignin to the surface.

3.1.1 Modification of Cellulose Fibers

Cellulose fibers are generally modified to improve adhesion, wettability and bonding properties. Surface modification is usually done by flame, plasma, corona, and chemical treatments. ESCA is ideally suited and primarily used to confirm the surface chemical compositional changes with respect to each of these treatments. Several examples of plasma treatment of cellulose fibers to enhance adhesion properties can be found in the latter part of this article.

Felix et al.\(^\text{[16]}\) reported significant compositional changes including the formation of new bonds, C═N, C═N, N-C=O, on the fiber surface when treated with ammonia plasma. Belgacem et al.\(^\text{[17]}\) studied the corona treatment of cellulose fibers by XPS. The corona treated fibers showed high levels of surface oxygen compared with untreated fibers, indicating corona-induced surface oxidation of impurities making the surface more hydrophilic. They also observed an increase in the carboxylic content (C4) of treated fibers at all corona current levels.

Apart from the more traditional uses of wood pulps, there has been a growing interest in the use of wood pulps in composite materials because of their excellent mechanical properties, low density, availability and cost. However, the problem of improving the compatibility between the hydrophilic cellulose fibers and hydrophobic synthetic polymers has been a major issue. As coupling agent, a bifunctional molecule is often used to overcome incompatibility between these two phases. Zadorecki and Flodin\(^\text{[18]}\) studied the grafting of trichloro-s-triazine-based coupling agents onto cellulose fibers to improve adhesion between fibers of cellulose and polyester. The amounts of oxygen and nitrogen were used for calculating the concentrations of cellulose and coupling agent, respectively. XPS data strongly suggested that the coupling agent concentrated on the treated fiber surface.

Kazayawoko et al.\(^\text{[19]}\) studied the reaction between bleached kraft cellulose and lignin and maleated polypropylene, a coupling agent. High-resolution carbon spectra of the treated pulps showed high levels of C1, compared with untreated pulp, indicating surface enrichment of aliphatic carbon due to a polypropylene backbone. The appearance of C4 (O-C=O) in the treated pulps indicated an esterification reaction between the hydroxy groups of cellulose fibers and anhydride groups of maleated polypropylene.

XPS has also been used to study the weathering of wood. Wood surfaces when exposed to natural environmental conditions, such as moisture, ultraviolet radiation and fungi, undergo discoloration and erosion. Lange et al.\(^\text{[20]}\) measured the O/C ratios of European pine wood weathered at variable times after treating with CrO3 and NaOCl solutions. The increase in O/C ratio, which signifies weathering, was found to be much slower for CrO3-treated wood, compared with the increase in untreated wood. Kaldas et al.\(^\text{[21]}\) used the C1/C2 ratio to determine the progress of the oxidation of wood treated with chromated copper arsenate (CCA) solution. The variation in this ratio suggested that oxidation of C2 (C═OH, cellulose) predominated on initial contact with CCA solution but the oxidation of C1 (C═C, lignin) became more important with extended exposure to the treating solution.

XPS has been proven to be a valuable tool for the characterization of chemical and mechanical pulps and pulps which are chemically modified to enhance certain properties. XPS could also be used as a problem solving tool. For example, first the fiber strength and performance issues could be addressed by measuring the surface lignin, extractives or other contaminants which interfere with the hydrogen bonding of fibers; and, second, washing and bleaching efficiencies of the manufacturing process could be found by measuring the enrichment of chemical contaminants on the fiber surface.

3.2 Coated Papers

Pigment coatings are applied to paper to improve printing characteristics. The coating mixture, which is commonly referred to as coating color, is applied as an aqueous slurry of three basic components: pigment, binder, and minor amounts of other additives such as lubricants and viscosity modifiers. Pigments which represent the largest portion of a dried coating, (75–90% by weight of the total solids) are naturally occurring clay and calcium carbonate. Binders are those materials which cause coating pigments to be bonded to each other and to adhere to the paper base. All coating binders are natural or synthetic organic polymers such as starch, styrene–butadiene rubber latex (SBR) or acrylic lattices. TiO2 is often used to meet the optical properties of lightweight coated (LWC) papers. If the sample is an unknown, a survey spectrum is useful to qualify the elements in the target sample (see Figure 1). Most of the literature published has been focused on the application of XPS to measuring the concentrations of pigment and binder (P/B) in coated papers. The P/B ratios vary significantly depending upon the grade, and
also heavily influence the final properties (print, optical and physical) of the coated papers.

Fujiwara and Kline\textsuperscript{22} described a method for determining the surface concentrations of binders and pigments in multicomponent coated papers. A series of model papers was prepared with known concentrations of SBR latex–starch binders and clay/\(\text{CaCO}_3\) pigments, and analyzed by XPS. Using the atom-percent concentrations from the XPS data for calcium, silicon and high-resolution carbon, they have developed a series of numerical equations for calculating the coating composition. In their calculations they assumed that the total C1 and C2 signals were primarily due to SBR latex and starch, respectively. The method works extremely well for simple coating systems. But the P/B ratio calculations for unknowns would become complicated if the samples contained plastic pigment or if the paper is only partially covered, exposing fibers on the surface. Our experience of coating composition calculations using the method of Fujiwara and Kline has been successful in most cases but the concentrations of latex and starch have always been found to be higher than what was in the original coating color. This might be due to the presence of other coating components such as thickeners and dispersing agents and uncoated fibers which might contribute to the total C1 and C2 signals.

The studies of Tomimasu et al.\textsuperscript{23,24} of coated papers represent a comprehensive investigation of the effects of pigment composition, particle size, surface roughness, drying temperature on the surface binder concentration, and \(z\)-directional distribution of binder. The signals from starch and latex were differentiated using fluorine-labeled latex. The binder concentrations were represented as C1/Si (or Ca) ratio. From the XPS data, they concluded that the binder/pigment ratio \((a)\) was not affected by supercalendering, \((b)\) was extensively affected by pigment particle size and \((c)\) that SBR latex selectively migrated to the surface rather than starch.

Strom and Carlsson\textsuperscript{25} showed that the elemental composition was independent of the sampling depth indicating that the coating surface is homogeneous in the \(z\)-direction within that sampling depth. The dispersion agents in the pigment slurries were expected to form a thin overlayer, but the angle-dependent work showed otherwise. The apparent area fraction or the concentration of binder decreased with increased pigment particle size. The effects that binder type and pigment level have on the surface chemical compositional changes of laboratory and pilot-coated samples were also investigated. Paper gloss increased with an increase in surface pigment \((\text{clay})\) concentration.

Gron and Strom\textsuperscript{26} studied the effect of binder type on the surface chemical composition of coated papers using cationic and anionic starch. From the XPS data for nitrogen and clay \((\text{Al and Si})\) they concluded that cationic starch is more on the surface and covered the pigment particles more efficiently than anionic starch. Also, the C2 content (assumed to be due to starch) was twice as high on the surface coated with cationic starch than that of the surface coated with anionic starch.

Brungard and Cleland\textsuperscript{27} reported the use of XPS to estimate the concentrations of clay, TiO\(_2\), and CaCO\(_3\) pigments in coated papers. They showed that more accurate concentrations of these pigments in coated papers can be obtained only when empirical calibration data rather than calculated peak sensitivity factors were used. Empirical calibration curves were generated from the XPS data using various but known concentrations of three pigments and binder systems. The XPS pigment-to-matrix ratio data were always lower than the theoretical ratio calculated from the component weight percents. They showed that calendering, coat weight, and the type of binder did not significantly affect the pigment concentration measurements. TiO\(_2\) could not be quantified above 1% due to overlay of Al\(_2\)O\(_3\) which is normally deposited on TiO\(_2\) particles surfaces to improve dispersion.

### 3.2.1 Binder Migration and Print Mottle

Print mottle problems have often been attributed to selective migration of binder (starch or latex) to the surface or to the base. The process of migration is very complicated and is influenced by several factors, including coating composition, percent solids, binder type and level, base stock, and drying rate. A detailed discussion of various parameters and their effects on binder migration is beyond the scope of this article. Print mottle is often attributed to the nonuniform absorption of ink due to defects in the coated surface, resulting in areas of high and low print gloss. Areas of higher surface binder content may receive less ink than those of lower binder content resulting in print mottle. Other forms of print mottle, such as back trap mottle and water-interference mottle, can also occur as a result of transfer of ink from one blanket to the other printing blanket in a multicolor printing process. A few examples of how XPS technique was used to determine the migration behavior and its effect on print mottle are discussed. XPS has successfully been used, in some cases, to prove or disprove the migration behavior of binders in coated papers.

Engstrom, Strom and Norrdahl\textsuperscript{28} studied the effect of coating drying process on the binder migration and on print mottle. The atomic ratio \(N_C/N_Si\), where \(N_C\) represents the binder (latex + starch) and \(N_Si\) represents the clay concentration, was used for quantifying the surface concentration of binder. The greater the ratio, the more binder is present in the coating surface. The print mottle, as measured by the Croda print mottle test, decreased with an increase in the evaporation rate, but
the ESCA experiments showed no significant difference in $N_C/N_S$ ratio, implying that binder migration was not influenced by evaporation rate. In other experiments, in which differing coat weight papers samples were examined, mottle increased with increased $N_C/N_S$ ratio. It appears from these results that evaporation rate is less important when compared with the available water phase for evaporation for migration to occur. The binder migration increased when the time between the coating application blade and the dryer was increased. Application of fluid coating colors onto the surface of a porous paper base and their exposure to elevated temperatures in drying systems results in migration of and redistribution of the aqueous binder as long as there is sufficient mobility in the freshly applied coating color.

Arai et al. established a strong correlation between binder-to-pigment ratio and print mottle. By selecting an effective XPS measurement width close to the size of the mottling pattern, XPS spectra were obtained by scanning the coated surface across the entire mottling area. The binder distribution, which was evaluated as the ratio of binder to pigment, was plotted against the scanning length. The coefficient of variation in the data was used as an indication of mottling tendency of the papers. The print mottle was found to correlate well with the binder-to-pigment ratio and was independent of $z$-directional distribution of coating components.

Yamazaki et al. studied the effects of binder migration and latex film formability on print mottle using laboratory and pilot-coated paper samples. The time interval between the coating application and drying was varied to determine the migration tendencies of starch and latex. By comparing the surface concentration with the concentration in the coating color they showed that latex and starch migrated differently. The surface latex concentration was unaffected by the time interval. The starch, on the other hand, migrated either to the surface or to the base sheet depending upon whether the time interval was low or high, and was more sensitive to coat weight. Although they could not establish an obvious relationship between the mottling tendency and surface starch, the samples in which the starch migrated towards the coated surface showed severe mottle. Since starch migration was found to be much more sensitive to drying time interval and coat weight, they concluded that starch has more influence on print mottle.

Zang and Aspler measured the print density on different model papers and showed how surface binder distribution differences affected the amount of ink transferred to the coated papers. Model samples were prepared by applying the coating colors to a commercial LWC paper base and to a nonabsorbent Mylar film and were allowed to air dry. The idea here was that the direction of binder migration depends on the relative rates at which water is drained into the basestock and at which water evaporates from the coating surface. In the case of LWC-coated samples, water flows towards the basestock causing the binder to migrate towards the basestock. On the other hand, in the case of Mylar film, water evaporates mainly from the surface causing the binder to migrate towards the surface. XPS results were used to support their binder migration mechanism theory. By assuming that the carbon content is a measure of latex content, they showed that the surface latex content at a given latex addition level was higher for the coatings on Mylar than for those on LWC paper. For coatings prepared under identical formulation, the amount of ink transferred to the coatings was less on nonabsorbent Mylar than to those on LWC paper due to differences in surface binder content.

Kim et al. studied the effects of binder type, drying temperature, and solids content on back-trap mottle. XPS data was used to help quantify the degree of binder migration of several pilot coated samples under different experimental conditions. The XPS data taken at 1 mm increments provided the confirming support to the coated paper which was most resistant to mottle. The distribution of the atomic concentrations for mottle-resistant coated paper was more consistent (less variation) than other coated papers which exhibited large variations in the atomic concentration data. The high C/Ca (binder/pigment) ratios suggested high binder content for two coatings when harsh late-drying temperatures were used. These observations suggested that the binder type and drying temperatures have strong influence on the binder migration behavior and print mottle.

Sanders and Bashey reported the application of XPS for solving a few common web offset printing problems, dusting, milking or glazing and scum deposits, which are directly related to paper/press interactions. Milking or glazing are typically white deposits on the printing blanket while the scum is a deposit along edge of the printing area. ESCA analyses of the clean blanket, glaze, scum, ink and paper showed that the major chemical surface constituents of the glazed area were phosphorus and calcium. Phosphorus, derived from the fountain solution, reacted with the calcium from the alkaline paper under acid conditions forming an insoluble calcium hydrogen phosphate which was deposited on the blanket. The scum (edge deposit), rich in organic nitrogen, originated from the ink. Similarly, image area deposits and the loss of print density problems of the coated papers have also been resolved using XPS.

The binder migration and print mottle of coated papers are influenced by several factors: base stock, choice of pigments, choice of binders, the drying process and percent solids. Each one of these factors has a small
or large influence, depending on the situation, on the migration behavior. However, severity of the migration and mottle behaviors are often the result of the severity of the experimental conditions and associated with the combined effect of various factors involved.

### 3.3 Nonimpact Printing Papers

#### 3.3.1 Laser Printing Papers

Various functional properties of laser, xerographic, and electrophotographic papers have been discussed in the literature.\(^{34,35}\) The paper designed for laser printing should be resistant to heat, pressure, and curl, and also should possess other properties such as smoothness, electrical resistivity, percent moisture for its optimal performance. One of the major attributes of electrophotographic paper is toner adhesion. Toner adhesion or fusing fix is described as how well an image is fused to the paper and its resistance towards scratching.

Unlike other conventional printing processes, the molten toner in the laser printing process does not enter into the fiber walls nor does it penetrate deep into the paper. Because the interaction of the toner is limited to the surface of the paper, the surface chemistry and the surface energetics of the paper play a major role in the print quality and toner adhesion of laser papers. XPS studies of electrophotographic papers have been used for studying toner adhesion problems and for identifying contaminants on paper surfaces.\(^{35}\) Contaminants such as waxes or adhesives are detrimental to the performance of the printer.

Farrow et al.\(^{36}\) studied by XPS the surface chemistry of several papers with varying pulp composition, internal size, and external size and correlated the surface hydrocarbon component (C1) with toner adhesion. Increased levels of C1 component reduced toner adhesion. Sanders et al.\(^{37}\) studied the surface composition of 25 model papers, which had different levels of internal size, external size, and fillers. The model papers were printed on three different high speed copiers and the degree of fusing fix was correlated with the surface energies of the papers. The changes in the surface energies of these papers were explained in terms of the C1 concentration. Borch\(^{38}\) had shown that there is considerable variation in toner adhesion depending on the additives used for sizing papers. The variation in the toner strength was attributed to the changes in the surface energetics.

XPS analyses of 20 uncoated commercial laser papers were performed in our laboratory. They exhibited a wide range of surface elemental compositions depending upon the type of sheet: acid, alkaline, sized or unsized. From these data a typical range of chemical composition for laser papers can be drawn (Table 3).

Calcium, silicon and aluminum originated from filler materials. Sodium might be due to common salt and/or from the surface sizing additive. It is a common practice to add sodium chloride to xerographic papers to control the electrical properties of the paper.

#### 3.3.1.1 X-ray Photoelectron Spectroscopy Analysis of Toner Films

Toner adhesion not only depends on the substrate (paper) but on the toner characteristics as well. It is therefore desirable to understand the composition and the chemistry of toners.

XPS spectra of freshly prepared molten toner films from three different manufacturers were obtained. The XPS data are shown in Table 4. From these results, it is evident that all three toners are distinctly different with respect to oxygen, carbon and silicon contents. The percentages listed in Table 4 are the surface concentrations of various elements and are not to be confused with the bulk composition which could be quite different. However, in all cases, the observed carbon was totally in the C1 form, indicating that the toner surfaces are very hydrophobic.

Most xerographic toners are low surface energy materials primarily composed of either styrene/acrylic-based, polyester-based, or pure acrylic-based polymers. High-resolution spectra of silicon exhibited a broad peak with a shoulder indicating two forms of silicon. Based on the binding energies of the silicon peaks (104.2 eV and 102.5 eV) it is assumed that the two peaks represent inorganic (SiO\(_2\)) and organic silicon. It is known that organic silicon compounds are used in toners to control the fluid properties of the toner. Inorganic SiO\(_2\) particles are used to coat toner particles to

prevent toner particle–particle agglomeration. The toner chemistry is very complex and ever changing. It is not the intention of this paper to provide a detailed description but to make the reader aware of the importance of differences in toners when evaluating the papers for toner adhesion.

The surface energy of the paper should be higher than the surface energy of the toner for it to be wetted by the molten toner. Tirtaamadja et al.\textsuperscript{39} reported surface energies of several electrophotographic papers which ranged between 25 and 34 dyn cm\textsuperscript{-1}, which are well above or close to 26 dyn cm\textsuperscript{-1} surface energy reported for styrenated molten toner. Internal sizing agents such as alkyl ketene dimer (AKD) and alkyl succinic anhydride (ASA) have been known to reduce the surface energy of the paper substrate resulting in poor toner adhesion. Surface sizing agents such as styrene maleic anhydride (SMA) have been reported to improve the toner adhesion due to compatibility between the toner resin and SMA. It should be noted that toner adhesion and print quality are complex phenomena which on balance are the result of reaching a desirable compromise of many paper properties including the surface chemistry. A preliminary investigation of toner adhesion tests for about 11 commercial papers showed a correlation with O/C ratio. As the O/C ratio is decreased, toner adhesion was found to be increased.

### 3.3.2 Ink Jet Printing Papers

The requirements for ink jet papers are radically different from laser papers. In ink jet printing, uniformly shaped droplets of aqueous dye solutions are jetted on to the paper to form the image. The paper structure and surface chemistry requirements for good print quality are so unconventional that new paper grades specifically designed for ink jet printing are being marketed. The three most important requirements for coated or uncoated paper for ink jet applications are:

1. rapid but controlled absorption of liquid ink to prevent smearing and feathering;
2. shallow penetration of liquid ink (lateral spread) into the base sheet to prevent show through;
3. the dye in the solutions should permanently bond to and stay on the surface.

The dye retention and the absorption of the water to a large extent are surface phenomenon whereas the lateral spread of the water depends on the bulk composition of the coating and the base stock.

The performance of various specially coated and surface-sized papers was discussed by Lyne and Aspler.\textsuperscript{40} To obtain optimum color quality and permanence, most paper manufacturers developed new coatings and sizing additives specifically for ink jet applications. Most of these additives are patented or kept as trade secrets. The most common ink jet coatings consist of silica, calcium carbonate or clay or a combination thereof as pigments and poly(vinyl alcohol) (PVOH) or starch as binder. Poly(vinyl pyrrolidone) (PVP) is often used to improve ink receptivity.\textsuperscript{41} In very specialized coating applications, a cationic polymer, such as quaternary ammonium (QA) salts, is used for dye fixation and improved print quality.\textsuperscript{42} We have performed XPS analysis of several ink jet papers and the results are shown in Table 5. All paper samples analyzed were either commercially available or given to us as free samples at trade shows.

Most of the uncoated papers, both acid or alkali, have been claimed for multise, i.e. for copy, laser and ink jet printing. About 23 such paper samples were analyzed and the composition was found to be in the ranges of O, 32–39%; C, 58–68%; and minute amounts of filler materials, either clay or calcium carbonate. The O/C and C2/C1 ratios of uncoated samples were in the ranges of 0.4–0.6 and 0.7–2.0, respectively.

The coated papers or papers with special treatment specifically designed for ink jet applications exhibited complex surface chemistry. Although each sample is distinctly different with respect to the concentrations of each element, all of them contained high levels of silicon and nitrogen. Silica pigment, owing to its high-surface area and high-internal pore volume is commonly used

\textsuperscript{a} Also contained low levels of calcium. Numbers might not add to 100% due to rounding of numbers and omission of elements of low concentrations. N(T) = total nitrogen, N(Q) = contribution from QA salt to the total nitrogen.

X-RAY PHOTOELECTRON SPECTROSCOPY, PAPER SURFACE ANALYSIS BY
as a hydrosink for the absorption of water in the ink. Some coated papers exhibited two peaks for nitrogen, 399.5 eV and 402.5 eV as shown in Figure 3. Comparing the binding energies for standard reference materials with the binding energies for the samples, we theorized that the peaks for nitrogen at 399.5 eV and 402.5 eV may have been respectively due to nitrogen in PVP and QA salt. The XPS spectrum alone can not identify these compounds. Based on this assumption the respective amounts for the total nitrogen and QA salt were calculated.

The performance of ink jet paper depends on several factors including the type of silica, types of PVP, PVOH and any other ingredient that might be present in the coating formulation. New coating formulations are constantly being developed to improve and/or add certain attributes to the paper quality. The purpose of this analysis is only to demonstrate how XPS techniques can be used for analyzing the surface chemistry of ink jet papers. It should be pointed out that knowledge of the surface composition, which could be different from the bulk composition, would not alone be sufficient to develop paper coating with superior performance.

3.4 Adhesion

XPS has been proven to be the most valuable tool for addressing adhesion-related problems. The XPS method provides distinctive signatures of any contaminants on the surface which might interfere with adhesion. In the food packaging industry, good adhesion between the board and the plastic is important and critical for the functioning of the package. Milk, juice cartons, and paper coffee cups are made of polyethylene extruded board. In order for the plastic to adhere, the surface energy of the board should be higher than that of the plastic. Wet strength resins and internal sizing agents are added to the basestock to impart wet strength to the food board. Like the plastics, these are low surface energy materials which reduce the surface energy of the board if present excessively on the surface. This reduced surface energy results in poor bonding between the board and polyethylene. The weakly adhered polyethylene would ultimately be delaminated due to mechanical forces during carton manufacturing, printing or when exposed to liquids. Critical reviews of other factors affecting the adhesion of polymers to the surface are available in the literature.

The capability of XPS to deal with adhesion problems was demonstrated by Istone. He showed that the C1 component of the problem board was significantly more than the good board causing the surface energy of the problem board to be lower. Wet strength was ruled out as the source of the contamination since the resin used was a polyamide and no nitrogen was observed in the XPS spectrum. AKD, which was used as an internal sizing agent, has very low surface energy (18 dyn cm\(^{-1}\)) and was found to be the source of C1 contamination of the surface.

Westerlind, Larsson and Rigdahl evaluated the degree of adhesion between greaseproof paper and low-density polyethylene (LDPE) using XPS. The paper and LDPE samples were plasma treated in the presence of ammonia and oxygen. The XPS analysis of the untreated and plasma-treated samples showed a dramatic increase of oxygen amounts both on the greaseproof paper and LDPE. The significant improvement in the adhesion between the plasma-treated paper surface and LDPE was explained by the incorporation of polar oxygen and nitrogen-containing groups. These polar groups increase
the surface energy and wetting properties of the paper surface causing the polyethylene melt to penetrate into the fiber network.

Nussbaum\(^{44}\) reported the use of XPS to evaluate the glue adhesion property of flame-treated wood surfaces. The O/C ratio was found to increase from 0.24 for untreated pine wood to 0.57 for flame-treated pine wood. The high-resolution C (1s) spectra showed a dramatic increase in the C2: hydroxy or ether and C3: carbonyl groups. Although flame treatment led to a remarkable increase in the wettability and surface oxidation level of the flame-treated wood, no distinguishable improvement was observed with the glue, indicating that some other adhesion mechanism was operative.

Carlsson and Strom\(^{9}\) measured the surface composition of hydrogen and oxygen plasma-treated filter paper and greaseproof paper by XPS. They showed that surface chemistry was very important for good adhesion between these papers and polyethylene. The changes in the adhesive strength between modified and unmodified papers and polyethylene were discussed in terms of the changes in the O/C ratios of the papers. A small decrease in the O/C ratio produced a large decrease in adhesion.

XPS can also be applied to the study of adhesives. Often the adhesion failure between the paper and adhesive might be due to the incompatibility and/or poisoning of adhesive resins. Brewis et al.\(^{45}\) studied the loss of adhesive strength of adhesives treated with zirconium solutions which are added in the recycling industry to make stickies less tacky. XPS analysis of adhesives treated with zirconium acetate and ammonium zirconium carbonate solutions showed that zirconium was absorbed in all adhesives tested. Ammonium zirconium carbonate has been used in the paper industry for several years as a sizing agent in certain applications. XPS analysis of envelopes in our laboratory with poor and good adhesion showed the presence of zirconium on the surface of the envelopes with poor adhesion. Zirconium has a strong affinity for oxygenated species and readily interacts with the functional groups of the adhesive. It may be that the zirconium on the problem paper surface readily attached to the adhesive reducing its adhesive strength by blocking off the functional groups which otherwise bond to the fibers on the surface.

Hemmingen\(^{46}\) used ESCA to study the extent of wax bloom to the surface of latex-coated papers. Wax is used in top coat latex formulations to improve antiblocking and slip properties. Podhajny\(^{47}\) suggested a strategy which involved the use of ESCA when FTIR failed to identify the cause of poor heat seal problem with paper/poly/foil/polyethylene base stock.

### 3.5 Paper Additives

#### 3.5.1 Surface Size Analysis

One of the important properties of paper is its resistance to wetting. Paper, if untreated, absorbs water because of its high porosity and hydrophilic nature due to the presence of hydroxy groups of cellulose and hemicellulose. To impart water resistance, most commodity papers are manufactured with internal sizing agents, hydrophobic low-surface energy materials which are added to the papermaking stock before the sheet is formed. These internal sizing agents, which must attach to the fibers through the use of an appropriate functional group, present a hydrophobic surface on the fiber. The major internal sizing agents used commercially are fortified rosin, ASA and AKD. XPS has been used to study the migration of these sizes to the surface and their adverse effects on adhesion.\(^{35}\)

Surface sizing agents, on the other hand, are applied as a solution to the surface of the paper after it has been formed. Papers that are to be surface sized often already contain internal size to regulate penetration of the surface-sizing materials into the sheet structure. The primary purpose of the surface size is to improve the print quality although several other benefits can be achieved. Surface sizes can either be hydrophilic (such as starch, carboxymethyl cellulose, PVOH) or hydrophobic (such as SMA, polyurethane or styrene acrylic polymer). The hydrophilic sizes improve water resistance by filling the voids and sealing the sheet which reduces the absorption of water by capillary action. However, the nonpolar synthetic polymers form a film on the surface of the paper. The film minimizes water absorption, improves ink holdout and improves surface picking resistance.

XPS can be readily used for detecting low levels of surface size on paper. Brinen et al.\(^{48}\) reported quantitative determination of \(N,N,O\text{-tris(octadecylcarbamoyl)}\)hydroxylamine (HABI), an alkaline size, on paper surfaces by XPS. As the amount of HABI applied increased, the amount of C1 present on the surface was increased. A linear relationship was established between the C1/O and N/O ratios and the amount of HABI applied. More recently, Brinen\(^{49}\) reported a similar increase of the C1 component of papers sized with internal and external sizing agents.

Several other reports exist in the literature showing the distribution of sizing agents by time-of-flight secondary ion mass spectrometry (TOFSIMS).\(^{50}\) In our laboratory, we have also studied the XPS analysis of papers sized with three different synthetic polymers and the results are shown in Table 6. Because of the application of these sizing additives at very low levels, complete coverage of the paper surface is not expected. As a result, the sized papers exhibited XPS survey spectra very similar to the

SAP, styrene acrylic polymer; AAL, alkyl acrylic latex.
a All XPS spectra and results presented in this chapter were generated by the author on the Perkin-Elmer PHI-5500 Multi-Technique System at Champion International Corporation in West Nyack, NY. All experiments were performed using monochromatic aluminum X-rays (Kα = 1486.7 eV) at 400 W (15 keV). The survey spectra were acquired at a pass energy of 93.9 eV whereas the multiplex spectra were acquired at a pass energy of 58.7 eV. The analysis area was about 800 µm in diameter. High-resolution carbon spectra were obtained at pass energies of either 58.7 eV or 5.87 eV. Curve fitting and quantitation were performed using routines provided by the PHI instrument software. In all cases the experiments were performed on three different sample locations and an average was calculated.
b Reference material, applied as thin film on the paper and dried at 60 °C. C1(f) = Total C x (C1/100).

The differences observed in the O/C ratios of papers sized with synthetic sizes were only minimal and did not directly correlate with the O/C ratios of the synthetic polymer reference standards. Since the synthetic sizing agents are generally carbon-rich, the C1 component of the surface-sized paper is increased relative to the starch-sized papers as shown in Table 6. The C1 fraction (i.e. percent of total carbon present as C1) increased with the increase in the C1 fraction of the standard reference materials.

3.5.2 Coefficient of Friction

The application of XPS for studying the frictional properties of papers is rather limited in the literature. Frictional properties of paper, measured as static or dynamic coefficient of friction (COF), play a major role in the use and handling of paper. The frictional properties for each grade of paper should be optimized; if not, the paper either slips or cause excessive wear on the machines in high-speed converting and/or printing operations. A good account of various factors affecting the COF of paper and application of XPS for studying COF is given by Gurnagul et al. They found a linear relationship between the surface O/C ratio and static COF for newsprint samples. Increased levels of carbon (low O/C ratio) decreased the static friction between two papers. The differences in the amounts of surface carbon were attributed to the extractives present on the surface of the newsprint. The report also showed that corona discharge treatment of the newsprint samples showed a 30% increase in the COF due to increase in the surface oxidation of extractives on the surface. The O/C ratio increased from 0.39 for untreated to 0.47 for treated samples.

XPS and COF data were obtained in our laboratory for several commercial xerographic papers. All the samples were analyzed as received and consisted of both acid, alkaline, US and European sheets. The O/C ratio for each sheet was calculated and plotted against the static (paper against paper) COF in Figure 4. Even though there is a lot of scatter in the data, the trend, i.e. decrease in COF with the decrease in O/C ratio, is readily apparent. A linear relationship is not expected since several factors influence the COF; fiber, surface additives, surface extractives, pigments, filler type, and filler levels. Other factors which influence the COF are internal sizing agents such as ASA and AKD.

![Figure 4](image-url)  Plot of static COF as a function of O/C atomic ratio.
X-rays will be a valuable tool to determine and optimize the variables affecting COF. For example, XPS can be used to determine a threshold level for an internal sizing agent, or wet strength resin, for a given grade of paper, filler and fiber, before COF would become unacceptable. However, surface chemistry and chemical composition cannot alone define the frictional properties of paper. For example, supercalendering of coated papers changes the frictional properties without adversely changing the surface chemistry.

ACKNOWLEDGMENTS

The author wishes to express his deep sense of gratitude and appreciation to the senior management (Dr G. Closset) of the Champion International Corporation, a leading manufacturer of paper and forest products, and to the management (Drs F. Antonucci, F. Renk and R. Thorman) of Applied Technologies (Technology arm of the Champion International) for time and permission to publish this article. The author also expresses his sincere thanks to Dr W. Istone (also of Champion International) for his valuable advice and encouragement over the years. Thanks are also due to Mr R. Stewart for reviewing the documents. The author would like to thank his wife, Anjula, for her love and patience.

PULP AND PAPER

Remote Sensing: Introduction

Paul M. Mather
The University of Nottingham, Nottingham, UK

Analytical chemistry is concerned with instrumental and laboratory measurements that are made in the context of particular problems or tests. One of the procedures employed in analytical chemistry is spectroscopy, which is used to measure the degree of absorption and scattering of electromagnetic radiation impinging on an object, or the characteristics of electromagnetic radiation emitted by an object, in order to identify and infer the properties of that object. This same procedure forms the basis of remote sensing of the Earth’s surface from aircraft and satellites. Furthermore, imaging procedures such as scanning electron microscopy (SEM) are widely used by analytical chemists; the link with imaging of the Earth’s surface by remote sensing is even clearer. Thus, the principles of interpretation of remotely sensed images are, consciously or otherwise, similar to those used by analytical chemists.

Digital images of the Earth’s surface taken from space have been available for more than 30 years. Early civilian applications of this space imagery were in the fields of weather forecasting and meteorology. Photographs taken by astronauts during the Apollo 9 mission in 1968 demonstrated that a wealth of cartographic, ecological and geological information could be derived from images of the Earth taken from orbital altitudes. Until this time, the main source of spatial information used by Earth scientists, cartographers and others was the air photograph. Space photographs from Apollo also showed the benefits of synoptic or broad-scale views of the Earth available from altitudes of several hundred kilometers.

The National Aeronautics and Space Administration (NASA), with the support of the US Department of Agriculture and the US Geological Survey, designed and built the first automatic Earth satellite system for terrestrial observations during the late 1960s. Called ERTS-1 (Earth Resources Technology Satellite-1), this satellite was launched successfully in 1972. It carried a scanning instrument called the MultiSpectral Scanner (MSS), which collected digital images of the Earth’s surface in four spectral wavebands (green, red, and two near infrared (NIR) bands) for an area 92.5 km on either side of the sub-satellite track. Its orbit was such that ERTS-1 could survey all of the Earth’s land and sea surfaces between latitudes 82°N and 82°S over a period of 18 days. In order to maintain consistency from one observation of a given point to the next, ERTS-1 had a near-circular, sun-synchronous orbit with a daytime equatorial crossing time of 0945 local time. On the launch of the second ERTS in 1972 the programme was renamed “Landsat” and, to date, seven Landsats have been launched. Landsats 1–3 were similar in design to ERTS-1, but Landsat-4 and Landsat-5 carried a more advanced sensor called the Thematic Mapper (TM). This instrument collects images in seven wavebands, from the blue-green end of the optical spectrum to the middle infrared. The spatial resolution (as measured by pixel size on the ground) of the TM instrument is 30 m compared with the 80-m resolution of the MSS. Landsat-6 failed to reach orbit, but Landsat-7 was launched successfully in 1999. It carries the Enhanced TM Plus (ETM+) instrument, which includes a panchromatic channel with a ground resolution of 15 m.

Landsat MSS images were intended primarily for use in agricultural crop monitoring and classification. However, it soon became clear that information relevant to a range of applications could be derived from MSS imagery. For example, Figure 1 shows a Landsat MSS image of the area around Phnom Penh, Cambodia, taken on 3 January 1973. This image is a color composite, in which ground-reflected solar energy in the spectral waveband 0.8–1.1 µm (NIR) is shown in red, ground reflection in the 0.6–0.7 µm (red) waveband is shown in green, and reflection in the 0.5–0.6 µm (green) waveband is shown in blue. Water bodies have low reflectance in the NIR band, with progressively higher reflectance in the red and green bands, depending upon the amount of sediment present in the water. So, for example, the turquoise band running from the top to the bottom down the centre of the image is a turbid river. The black linear feature running across the left side of the image is a river (or canal) of relatively clear water, and the separation between the clear and turbid water is clearly apparent in the lower left corner, where the two water features coalesce. Red areas are vegetated, as the degree of vegetation vigor is shown by the magnitude of the reflected energy in the NIR waveband.

Figure 2 shows the area around the city of Las Vegas, Nevada, in the same color composite format as Figure 1. In comparison with the Phnom Penh image, there is relatively little vegetation (red color) or water (black or turquoise color), though the layout of the city is clear, and the topographic and geological structures in the area on the right of the image centre are clear. Alluvial fans – composed of sedimentary debris laid down by ephemeral streams – are visible on the left side of the image.

Advances in sensor design over the past 30 years have produced significant improvements in the quality of the images returned to Earth from orbiting satellites.
Perhaps the most immediately impressive development has been in the spatial resolution of imaging sensors. Figure 2 shows the city of Las Vegas, Nevada, as seen by Landsat’s MSS. The first commercial satellite, IKONOS, was launched in September 1999 by the American Space Imaging Corporation. Figure 3 shows a portion of the first image received from IKONOS, covering the area around the Jefferson Memorial in Washington, DC. The spatial resolution of this image is 1 m. The IKONOS satellite also collects multispectral imagery with a resolution of 4 m. While the Landsat MSS image of Las Vegas gives us a broad picture of the city and its region, providing information on both the physical landscape and the density of the vegetation cover, the IKONOS image provides a level of spatial detail that was previously associated with aerial photography. The images of Death Valley shown in Figure 6 also demonstrate the effects of spatial resolution on image interpretation and use. The spatial resolution of the images shown in Figure 6(a–c) are 15 m, 30 m, and 90 m, respectively.

Quality is not measured solely in terms of spatial resolution. The term more properly refers to the appropriateness to the intended application of the geographical scale, plus the spectral, radiometric and temporal properties of the source of imagery. Spectral resolution refers to the number and location of the spectral wavebands in which data are collected by the instrument. The precision of the measurements (radiometric resolution) is reflected in the number of levels used in quantizing the signal (Landsat MSS had 64 levels, while the newer TM instrument measures reflectance on a 0–255 scale). Temporal resolution refers to the time between repeat coverage of a given area. The repeat cycle of an orbiting satellite is related primarily to the characteristics of the orbit, which - for most Earth observing satellites - is near-circular and polar (the exceptions being...
the geostationary meteorological satellites such as GOES and Meteosat). However, some instruments such as the high resolution visible (HRV) sensor carried by the French/Belgian/Swedish SPOT satellites can be moved laterally through ±30°. This capability allows the instrument to be pointed off-nadir and thus collect information for a specified target at a higher temporal frequency than would be the case for a nadir-pointing instrument. The SPOT HRV’s pointing capability enables the system to collect stereoscopic imagery, because the target can be observed from first one side and then the other on adjacent orbits.\(^\text{[1]}\) Further details can be found in the article *Satellite and Sensor Systems for Environmental Monitoring*.

The articles in this section deal with applications that cover a range of spatial scales, from global to local. Each of these applications requires data at a specific spatial scale, with measurements in a particular spectral band or bands, and with an appropriate temporal frequency. A number of operational and experimental Earth satellite systems are available to meet these different requirements. For example, the article *Biological Oceanography by Remote Sensing* considers the way in which information from satellite-borne scanners is used to assess the abundance of phytoplankton and the concentration of dissolved solids and sediment in the upper layers of the ocean. The biological productivity in the oceans, the optical properties of ocean water, the interaction of winds and currents with ocean biology, and the way in which human activities influence the oceans can be investigated using data from these scanners. An example is the Coastal Zone Color Scanner (CZCS) operated between October 1978 and June 1986, on board the Nimbus 7 spacecraft. The CZCS instrument was specifically designed to measure the main absorption bands of phytoplankton and algae, as shown in Figure 4. The use of satellite remote sensing to study and monitor sea ice is a second important practical application in the field of oceanography. It is covered in *Sea Ice Monitoring by Remote Sensing*.

As noted above, the properties of remote sensing instruments such as the Landsat TM or the SPOT HRV sensors can be summarized in terms of their spatial resolution (the resolving power of the instrument), spectral resolution (the number and width of wavebands in which data are collected), radiometric resolution (the signal-to-noise ratio) and the temporal resolution. Each instrument is designed for one or several related applications, and the contributions in this section of the Encyclopaedia survey specific application areas. These contributions can be divided into the following groups:

- cartography
- oceanography

The contributions in the section that focuses on oceanography are considered above. Cartographic applications use satellite-derived data to map the two and three-dimensional shape of the Earth’s terrestrial surfaces. The use of two-dimensional satellite imagery, particularly that derived from the SPOT HRV, to collect planimetric \((X, Y)\) information is well established. More recent developments now permit satellite-borne instruments to derive Earth surface elevations to decimeter accuracy or better. This technique is known as elevation modeling, and the product – a three-dimensional representation of the Earth’s surface – is termed a digital elevation model, or DEM. This information is of great importance to Earth scientists engaged in explaining and predicting the behavior of terrestrial systems. Elevation modeling using spaceborne data is discussed in articles *Elevation Modeling and Displacement Mapping using Radar Interferometry* and *Elevation Modeling from Satellite Data*. While the SPOT HRV instrument has been widely and successfully used to generate DEMs, recent research has involved the use of interferometric synthetic aperture radars (InSAR) which are capable both of measuring surface elevations and (in differential mode) of mapping ground displacements following, for
example, earthquakes. Optical mapping instruments such as those carried by SPOT and IKONOS provide stereoscopic images similar, in principle, to those acquired by aircraft. The SPOT satellite provides stereoscopic imagery with a ground resolution of 10 m, while the IKONOS spacecraft’s camera is capable of producing imagery that has a locational accuracy of 2 m horizontally and 3 m vertically.

Figure 5 shows the ground displacement that occurred between April and October 1994, in the region of Kilauea volcano, Hawaii. The image area is approximately 40 km by 80 km. The colors indicate the displacement of the surface in the direction that the radar was pointing. The radar data used to generate this image were acquired from the SIR-C instrument, developed by the American, German, and Italian space agencies. The ground surface shape was derived from two sets of synthetic aperture radar (SAR) images, collected during Shuttle flights in April and October, 1994. Each set consists of two radar images collected on different orbits. Height information for each set was determined using interferometric methods, and the difference (displacement) is calculated from analysis of the differences between the two sets of height measurements. This type of information is of value in delimiting the extent of earthquake activity, and in monitoring surface movements in tectonically active areas of the world.

Geological mapping and mineral resources exploration is a major area of terrestrial remote sensing applications, and these are described in two articles entitled Hyperspectral Remote Sensing: Data Collection and Exploitation and Imaging Spectrometry for Geological Applications. Instruments capable of collecting data for large areas of the Earth’s land surface in a large number of narrow spectral bands and at high spectral resolution and hyperspectral instruments is providing new opportunities for detailed geological mapping, especially in arid and semi-arid areas. The article on Stellar Spectroscopy shows that techniques used in terrestrial applications are equally relevant to the exploration of extra-terrestrial objects.

Figure 6(a) and (b) shows two examples of images collected by the Airborne Visible Infrared Imaging Spectrometer (AVIRIS) developed by the NASA Jet Propulsion Laboratory, Pasadena, California. This instrument collects information in 224 contiguous spectral channels between 400 and 2500 nm. It is flown on a NASA ER-2 aircraft (a modified U2) at an altitude of approximately 20 km. Image (a) is a composite, made up of data from three channels in the visible and NIR range of the AVIRIS. The bright red areas in this image show vegetation. Image (b) is also made up of three AVIRIS bands, located in the short-wave infrared region of the spectrum. The turquoise regions in the upper left corner delineate ground covered by limestone fragments. Image (c) was collected by the thermal infrared MSS and, in this image, surfaces with a quartz content are shown in red. The three images also show the impact of spatial resolution: image (a) has a spatial resolution of 15 m, while (b) has a resolution of 30 m. The thermal infrared image (c) has a resolution of 90 m.
Land cover change may result from a variety of factors. Human activity, in the form of agricultural practices, is one major driver of change. Economic activities, such as logging and forest burning, are also widely recognized as processes that have a global impact. The effects of global environmental changes also influence the nature of land cover. Land cover changes may also promote environmental change – this positive feedback loop is an important component of global climate models. Our knowledge of the distribution, status and dynamics of the Earth’s terrestrial vegetation is restricted and uncertain, and monitoring from space is perhaps the only feasible way of maintaining our awareness of these changes. Global Land Databases for Environmental Analyses considers ways in which data derived from remote sensing sources can be stored, managed and accessed, while Land Cover Assessment and Monitoring; Temperate Forest Resource Assessment by Remote Sensing and Tropical Forest Resource Assessment by Remote Sensing are concerned with different aspects of monitoring various types of land cover. As pressure on marginal lands builds, as a result of population increase, as exploration for minerals and hydrocarbons extends more widely, and as the effects of atmospheric pollution spread globally, so the capability to monitor and assess fragile ecosystems grows in importance. Semi-arid Land Assessment: Monitoring Dry Ecosystems with Remote Sensing and Polar Environments Assessment by Remote Sensing consider the impact of remote sensing technology on human ability to measure and assess change in two such fragile regions of the planet.

No survey of the applications of Earth observation by remote sensing would be complete without a survey of the methods used in processing the images acquired by aircraft and satellites. A wide range of processing techniques are required if uses of such images are to be valid and reliable. Correction of the raw data for flaws and deficiencies, calibration in order to recover radiance data from quantized counts, and geometric registration of the images with a conventional map coordinate system are needed if remotely sensed data are to be used with other geographical data in the solution of problems. Processing and Classification of Satellite Images summarizes the use of advanced pattern recognition techniques, such as artificial neural networks, in the generation of thematic maps from multispectral imagery. This type of information, derived from satellite and aircraft imagery, is now widely used in geographical information systems.

As population pressures increase, the future of the planet depends on the timely acquisition of data concerning the state of our environment, and the use of these data in monitoring and modeling change. Earth observation by remote sensing offers an effective and affordable way of collecting such data. The articles in this section provide an overview of the methods used in the application of remotely sensed data to a variety of environmental problems.

Biological oceanography may be studied from space using sensors on satellites that determine the color of the ocean. The presence of phytoplankton (microscopic algae) in the upper layers of the ocean changes the color of the water as seen from above. In simplified terms, this is due to the selective absorption of blue light by the phytoplankton pigments (primarily chlorophyll) which changes the appearance of the water from blue to green. These changes in color can be observed using a satellite-borne spectroradiometer that measures the water-leaving radiance in a number of bands in the visible part of the electromagnetic spectrum. The limitations of the technique are first, that only information on the phytoplankton in the upper layers of the ocean can be obtained (light does not penetrate very far into the ocean). Second, most of the signal measured by the satellite sensor originates in the atmosphere (due to the molecular and aerosol scattering of photons there), so careful correction for atmospheric effects is necessary if good ocean data are to be obtained. Of course, in the presence of clouds the sensor will not “see” the ocean surface at all, and no data will be obtained. Third, only one component of the ocean ecosystem, namely the phytoplankton, can be studied by this means. Despite these limitations, satellite observations of ocean color have given new insights into biological oceanography on a global scale that could not have been obtained by any other means of observation. Observations of ocean color have contributed to a better understanding of the biophysical interactions that determine the phytoplankton productivity, the seasonal and interannual variations of the phytoplankton biomass on global scales, and the role of phytoplankton in the climate system. They have also contributed to the improved modeling of biogeochemical processes in the ocean.

1 INTRODUCTION

The purpose of this article is to describe the application of satellite remote sensing techniques to the study of biological oceanography. In one sense it seems strange to think that a sensor (instrument) flying on a satellite several hundreds of kilometers above the ocean surface can tell us anything at all about the biology of the ocean. This initial reaction is to a large extent correct, in that measurements from space can only tell us something directly about one very specific component of the ocean biology. That component is the phytoplankton, microscopic plants that live in the near-surface waters of the ocean. The reason that this component can be observed from space is that the phytoplankton contain pigments that are necessary for photosynthesis (primarily chlorophyll-a) and their presence in the water changes the color of the water, as seen from above the sea surface, usually from blue to green. Thus a satellite-borne sensor that makes measurements in the visible part of the electromagnetic spectrum can be used to measure the change in color, and so provide information on the phytoplankton.

Given that only a single component of the ocean biological system can be measured from space, one might ask: why bother? Plankton are the most abundant life form in the world’s oceans, both in terms of weight and of numbers. Phytoplankton are microscopic plants, while zooplankton are the microscopic and small animals that feed on the phytoplankton. A cubic meter of seawater...
will contain millions of these small plants. Phytoplankton are the oceanic equivalent of terrestrial plants, forming the basic element of the oceanic food chain. The total phytoplankton biomass is greater than that of all the marine animals taken together (zooplankton, fish, and so on). In addition to their role in the food chain, they have a significant role in the world’s climate system. Their presence in the water causes light to be scattered and absorbed, which warms the upper layers of the ocean. They produce chemical compounds that escape into the atmosphere and have a role in the formation of clouds. More fundamentally, in growing they use carbon dioxide from the atmosphere that has been absorbed into the ocean. When they die, some proportion of the plankton fall out of the upper layers of the ocean and become part of the seabed sediments, thus removing carbon from the system. Therefore, phytoplankton have a major role in the global carbon cycle and may be important in either ameliorating or accelerating the effects of anthropogenic emissions of CO2 into the atmosphere. At the present time it is not known how the phytoplankton will respond to the warming occurring due to the increase of greenhouses gases.\(^1\)

The preceding paragraph shows the importance of phytoplankton and why measuring them and their behavior is necessary, but why do it from space? As noted above, phytoplankton are ubiquitous in the world's oceans, but the traditional ship-based methods of observation are unable to give a truly global view of the phytoplankton in the ocean. Thus observations from space are the only means of obtaining a global view. In order to understand the oceanic ecosystem, of which phytoplankton are just one component, ship-based and other types of measurements are still necessary. However, the ability to measure one component of the system from space has brought many new insights into the biology of the ocean on the global scale. These will be described later in this article.

There are, of course, drawbacks to measuring phytoplankton by satellite remote sensing methods. Since the measurement of ocean color is made using the visible part of the electromagnetic spectrum, the major problem that arises is the presence of clouds, which prevents the sensor from seeing the sea surface and thus making measurements. (Other satellite sensors that measure in a different part of the electromagnetic spectrum, particularly the microwave part, can see through clouds, but do not provide information on ocean biology directly).\(^2\) As some areas of the world’s oceans are more prone to cloud cover than others this could lead to bias in the measurements. A second problem is that of the depth of penetration of light into the ocean. The satellite sensor measures light exiting from the sea surface representing the end-result of complex interactions (absorption and scattering) of the light entering the ocean with the constituents (such as phytoplankton) present in the water, and the water itself. Depending on the constituents present, the exiting light represents information about the constituents over some depth (the details of this will be considered further below). This depth varies from place to place, so interpretation of the measurements may not be straightforward. A particular example of this problem is that of the so-called deep chlorophyll maximum.\(^5\) This occurs when the surface waters are depleted of the nutrients necessary for the phytoplankton to grow. Here the balance between the phytoplankton's need for light (available from above) and nutrients (available from below) to grow, means that the bulk of the phytoplankton growth takes place well below the surface and may not be visible to the satellite sensor. Thus any estimate of phytoplankton activity, particularly primary production, based on ocean color measured from space will need to account for this type of situation.

Despite the drawbacks mentioned in the previous paragraph, the ability to measure ocean color from space has brought many new insights into ocean biology and these will be described later in this article. To begin, a brief history of the measurement of ocean color from space will be given.

### 1.1 A Brief History of Ocean Color Measurements from Space

The first true ocean color sensor was the Coastal Zone Color Scanner (CZCS), which was launched by NASA (National Aeronautical and Space Administration) on the Nimbus-7 satellite in late 1978 and operated until mid-1986.\(^6\) This followed on from the work of Clarke et al.\(^7\) who showed that chlorophyll concentration in the ocean surface waters could be estimated from airborne measurements of the light leaving the sea surface. CZCS made measurements in four channels in the visible part of the spectrum, one channel in the near-infrared, and one in the infrared (IR) (see Table 2 for details of the sensor). The latter channel allowed simultaneous measurement of the sea surface temperature (SST), but failed early in the mission. In addition, the sensor showed degradation over the life of the mission, which meant that the data had to be carefully processed to take this into account.\(^8\) A final drawback was that data were not acquired continuously globally during the mission, owing to the limits of power and on-board data recording. Nevertheless, data from most parts of the globe were acquired and the first truly global picture of phytoplankton activity in the ocean was obtained by averaging the data over time.

The next sensor due to be launched was the Sea-viewing Wide Field-of-view Sensor (SeaWiFS) flown on SeaStar, but various delays meant the Ocean Color and
Temperature Sensor (OCTS) was launched first by the National Space Development Agency of Japan (NASDA) on ADEOS (Advanced Earth Observation Satellite). OCTS was operational from August 1996 until June 1997, when the ADEOS suffered a catastrophic failure (Tables 3 and 4). In addition to measuring ocean color, OCTS measured SST using channels in the IR. SeaWiFS, a collaborative venture between NASA and the Orbital Sciences Corporation (OSC), was launched in August 1997, shortly after the failure of ADEOS. It continues to operate well and provide data globally (Table 5). Both SeaWiFS and OCTS have more channels in the visible part of the spectrum than CZCS, and this allows for better retrieval of biological information from the ocean (see section 3).

Another sensor that is flying in space, on the Indian IRS-P3 satellite, is an experimental one developed by DLR (German Space Agency) in Germany, the Modular Optoelectronic Scanner (MOS). It was launched in March 1996 and does not provide global data. It does have similar channels in the visible part of the spectrum to OCTS and SeaWiFS, but a much narrower swath (200 km). Two further sensors capable of measuring ocean color are due to be launched. The Moderate Resolution Imaging Spectroradiometer (MODIS) is due to be launched by NASA on the first Earth Observing System (EOS) platform in late 1999.(9) The Medium Resolution Imaging Spectrometer (MERIS) is due for launch in early 2001 on the European Space Agency’s (ESA) satellite Envisat.(10) Both sensors have more channels than OCTS and SeaWiFS (Tables 6, 7 and 8). MODIS and MERIS are not just designed for ocean color measurements but will also provide data on the atmosphere, and on terrestrial vegetation. Finally, the experimental Ocean Color Imager (OCI) is due to be launched on the Taiwanese satellite ROCSAT-1 in 1999.

The above discussion has given details of the sensors that have specific ocean color capability, but it is also worth noting that other sensors that measure in the visible part of the spectrum have been used occasionally.(2) In general, these sensors are not sufficiently sensitive for ocean color measurements, an exception being the detection of coccolithophore blooms using the visible band of AVHRR (advanced very high resolution radiometer); an instrument designed for measuring SST. Owing to their high reflectivity, coccolithophores can be seen by less-sensitive sensors such as AVHRR (see section 4.1.3 below). In this article the focus will be on those sensors specifically designed for ocean color measurements.

In order to understand how it is possible to obtain information about biological activity from satellite ocean color sensors, it is necessary to consider first the behavior of light in the ocean. This is the subject of the next section (section 2). Following this a more detailed description of the sensors and algorithms used to retrieve ocean color and biological information is given (section 3). Finally (section 4) the application of that information to study ocean biology will be discussed.

2 LIGHT IN THE OCEAN

The subject of light in the ocean is a vast one, as evidenced by the more than one thousand references given in a standard text by Kirk.(11) It is not possible in a brief article to do justice to all these aspects, so the focus will be on those most relevant to the remote sensing of ocean color. In this context light will be taken to mean electromagnetic radiation of wavelengths ca. 400–700 nm, to which the human eye responds, and which plants, including phytoplankton, can use for photosynthesis.(11,12) In terms of color, blue light has wavelengths of ca. 450 nm, green light ca. 520 nm and red light ca. 650 nm. The light of wavelengths 400–700 nm is usually referred to as photosynthetically active (or available) radiation (PAR).(11,13)

2.1 Some Definitions

Light (photons) entering the ocean is subject to two physical processes, absorption and scattering (for more details of the definitions in this section see Mobley(14) and Kirk(11)). The description of the optical properties associated with these processes is usually divided into inherent and apparent optical properties (IOPs and AOPs). IOPs depend only on the medium and can be specified for light of any given wavelength λ by the absorption and scattering coefficients, a(λ) and b(λ), and the volume scattering function, which describes the directional properties of the scattering. The AOPs depend both on the medium (thus on the IOPs) and on the geometric structure of the ambient light field. Examples of AOPs are the diffuse, or vertical, attenuation coefficients K(λ, z), which describe the approximately exponential decrease with depth z of various properties of the light field. The IOPs and the AOPs depend on both the water and on what is in the water, for example, phytoplankton.

In terms of the light properties of interest in remote sensing, the important quantities are radiance, irradiance, upwelling (upward) and downwelling (downward) irradiance, diffuse attenuation coefficient, and the optical depth. These are all considered to depend on the frequency or wavelength of the light, as ocean color sensors measure light in discrete bands of the electromagnetic spectrum. Therefore, in terms of wavelength, they are expressed in units as per nanometer (nm⁻¹), that is per unit spectral bandwidth. Equivalent quantities integrated...
over part or the whole of the visible spectrum are defined without nm\(^{-1}\). Radiance \(L(\lambda)\) is the optical property appropriate to light energy leaving an extended source or incident on a surface, such as the ocean, and has units of W m\(^{-2}\) sr\(^{-1}\) nm\(^{-1}\). The last but one factor is per steradian, a measure of solid angle). Irradiance \(E(\lambda)\) is the radiant flux per unit area of a surface and has units of W m\(^{-2}\) nm\(^{-1}\). Downwelling irradiance \(E_d(\lambda)\) and upwelling irradiance \(E_u(\lambda)\), are the values of the flux passing down, or up, through a horizontal surface. \(E_d\) and \(E_u\) are obtained from \(L\), the radiance incident on the surface, by integrating with respect to the solid angle \(w\) for the upper and lower hemispheres, respectively, see Equations (1) and (2). Thus

\[
E_d = \frac{L \cos v \, dv}{\text{upper hemisphere}} \quad (1)
\]

\[
E_u = -\frac{L \cos v \, dv}{\text{lower hemisphere}} \quad (2)
\]

where \(v\) is the zenith angle. \(^{(11)}\) The diffuse or vertical attenuation coefficient at a depth \(z\) is given by Equation (3)

\[
K(\lambda, z) = \frac{-1}{E(\lambda, z)} \frac{dE}{dz} \quad (3)
\]

and has units of m\(^{-1}\). If \(K_d\) does not vary much with depth, an optical depth can be defined as \(1/K_d\), where \(K_d\) is the diffuse attenuation coefficient for the downwelling irradiance \(E_d\). It can be shown that the information on chlorophyll concentration obtained from an ocean color sensor is that from approximately one optical depth, which can be regarded as the depth that the sensor sees into the ocean. \(^{(15)}\)

The key quantity of interest in measuring ocean color from space is the water-leaving radiance \(L_w\). This represents the light leaving the sea surface resulting from the absorption and scattering by the water itself and by in-water constituents, such as phytoplankton, of light incident on the sea surface. It is this light that contains information about what is in the water. However, the light (radiance) that the satellite sensor measures \(L_s\) originates from a number of sources (see, for example, Robinson\(^{(2)}\) or Kirk\(^{(11)}\)). Even in relatively clear atmospheric conditions \(L_w\) is only 10–20\% of \(L_s\). \(^{(11)}\) This means that the effect of the atmosphere must be accounted for in deriving \(L_w\) from \(L_s\). This problem is discussed in section 2.3 below. For various technical reasons that will not be discussed here, two other related quantities are sometimes used in the measurement of ocean color rather than \(L_w\). These are the normalized water-leaving radiance; that is, approximately the radiance that would exit the ocean in the absence of the atmosphere and with the sun at the zenith. \(^{(16)}\)

Another alternative to \(L_w\) is the reflectance \(\rho_w\); that is, \(L_w\) normalized with respect to the extraterrestrial solar irradiance. \(^{(16)}\) The important point to note is that whichever quantity is used it can be related to the presence of phytoplankton in the water, which will be discussed in the next subsection.

The final definition to be given in this section is that of the euphotic zone. Kirk\(^{(11)}\) states that a useful rule of thumb in aquatic biology is that significant phytoplankton photosynthesis takes place down to a depth \(z_e\) at which the downwelling irradiance of PAR falls to 1\% of its value just below the sea surface. The layer in which \(E_d\) is greater than or equal to 1\% of \(E_d\) is known as the euphotic zone. It can be shown that the depth that the ocean color sensor sees into the ocean is approximately \(z_e/4.6\) (one optical depth). In waters with a low concentration of chlorophyll (0.1 mg m\(^{-3}\)) this depth is about 25 m, whereas for waters with a higher concentration (10 mg m\(^{-3}\)) it is about 5 m. \(^{(17)}\) High concentrations of chlorophyll reduce the penetration of light into the ocean, owing to absorption and scattering.

### 2.2 In-water Constituents and Bio-optics

In simple terms the presence of phytoplankton in the water changes the color of the water as seen by the color sensor. Waters low in phytoplankton pigments reflect more blue light than green, whereas waters high in pigments reflect more green light as a result of the selective absorption of blue light by the pigments. This means that the shape of the light spectrum changes and by measuring in different bands of the spectrum it is possible to quantify the concentration of pigment present in the water. \(^{(2,11)}\) The pigments that absorb the light are chlorophyll-a and phaeopigments, so the estimate obtained from the color data is the pigment concentration. However, the phaeopigments are a small fraction of the total (ca. 10\%), \(^{(18)}\) so the pigment concentration can be regarded as the chlorophyll-a concentration in the case of CZCS, owing to the inherent error in the algorithms used to recover this information (section 3.2). In the section on applications, the terms chlorophyll concentration or pigment concentration will both be used when discussing CZCS data. In order to extract the pigment concentration information from the ocean color measurements it is necessary to develop bio-optical algorithms and the theoretical basis of these is considered next.

It can be shown theoretically that the water-leaving radiance \(L_w(\lambda)\) is related to the reflectance \(R(\lambda) = E_u(\lambda)/E_d(\lambda)\) evaluated just below the sea surface. \(^{(2,15)}\) Theoretical modeling suggests that \(R(\lambda)\) in turn depends on the absorption \(a(\lambda)\) and backscattering \(b_s(\lambda)\) (note that the scattering coefficient \(b(\lambda) = b_s(\lambda) + b_t(\lambda)\), the scattering in the backward and
forward directions\(^{(11)}\). For \(b_b/a \) small, \( R = 0.33 b_b/a \);\(^{(2,19)}\) more generally \( R \) may be regarded as a function of \( [b_b/(a + b_b)] \).\(^{(12,20)}\) In addition, the absorption and scattering coefficients can be decomposed into the contributions due to the water itself and to each of the constituents in the water, and so related to the chlorophyll concentration. On this basis it is possible to develop what are known as semi-analytical models of ocean color, where the behavior of \( a(\lambda) \) and \( b_b(\lambda) \) is established through a combination of modeling and measurements.\(^{(20)}\) For CZCS the standard algorithms were in fact based on an empirical approach, where the ratio of the water-leaving radiance in two bands was compared to values of the pigment concentration measured in situ (section 3.2).\(^{(15)}\) This is a simple measurement that compares the water-leaving radiance in the blue to that in the green part of the visible spectrum, the ratio decreasing with increasing concentration of pigments.\(^{(20)}\) For future missions both empirical and semi-analytical approaches to estimating pigment concentration will be used (see, for example, Esaias et al.\(^{(9)}\)). In principle, the semi-analytical approach should provide improved information as it should reduce some of the uncertainties associated with the empirical approach.\(^{(20)}\) In either case accurate measurements of the water-leaving radiance in the sensor bands need to be obtained and this requires that the data be corrected for atmospheric effects, which are discussed next.

### 2.3 Measurements from Space and the Effect of the Atmosphere

It is well known that at least 80–90% of the signal received by an ocean color sensor at the top of the atmosphere originates from the atmosphere rather than the ocean, even in relative clear atmospheric conditions.\(^{(11)}\) In the presence of clouds no signal from the sea surface is obtained at all, of course. Therefore the removal of the atmospheric effects from the signal received by the sensor is crucial if accurate measurements of the water-leaving radiance in the various sensor bands are to be obtained. The signal received by the satellite sensor may be written as Equation \((4)\)\(^{(9)}\):

\[
L_a(\lambda) = L_t(\lambda) + L_a(\lambda) + L_{ra}(\lambda) + T(\lambda) L_{sg}(\lambda) + t(\lambda) L_{wc}(\lambda) + t(\lambda) L_w(\lambda)
\]

where \( L_t \) is the scattering of the photons due to air molecules (known as Rayleigh scattering), \( L_a \) is the scattering due to atmospheric aerosols (dust, water droplets, salt, and so on), \( L_{ra} \) represents interactions between the two previous effects, \( L_{sg} \) is the sunglint contribution (the direct reflection of sunlight from the sea surface), \( L_{wc} \) is the whitecap contribution (due to the presence of breaking waves), and \( L_w \) is the desired water-leaving radiance. \( T \) and \( t \) are the direct and diffuse transmittance of the atmosphere, that is the effects of the atmosphere on the signal from the sea surface. Sunglint cannot be corrected for, so data contaminated by sunglint are usually discarded.\(^{(16)}\) Considerable effort has been devoted to obtaining accurate corrections with regard to the other terms. Gordon\(^{(16)}\) gives a comprehensive review.

As the applications discussed later are based on data from the CZCS instrument, a brief explanation of the atmospheric correction technique developed for it will be given here. The ability to correct for atmospheric effects is partly dependent on the measurements made by the sensor. If measurements are obtained in a sufficient number of independent bands in the electromagnetic spectrum, then the effects of the atmosphere can be accounted for (to a lesser or greater degree depending on what is in the atmosphere). As CZCS had only four bands in the visible, the possibilities for atmospheric correction were limited, so simplifying assumptions were made. In particular, the Rayleigh scattering was assumed to be single scattering (photons have only one scattering encounter with air molecules) and this can be calculated theoretically, as can the diffuse transmittance of the atmosphere. The interaction term between the aerosol scattering and Rayleigh scattering term was ignored (being a secondary effect). The effect of whitecaps on the sea surface was also ignored.

The aerosol scattering term was treated in a simplified manner (see the appendix of Gordon et al.\(^{(20)}\)). If the water-leaving radiance is known in two bands at one position then the ratio \( S(\lambda_1, \lambda_2) = L_a(\lambda_1)/L_a(\lambda_2) \) may be found \( (L_w \) known, \( L_a \) measured, \( t \) and \( T \) calculated, all other terms ignored). Making the assumptions that the aerosol scattering phase function is approximately independent of wavelength, it can be shown under the single scattering approximation that \( S(\lambda_1, \lambda_2) = \varepsilon(\lambda_1, \lambda_2) F(\lambda_1)/F(\lambda_2), \) where the Fs represent the ratio of the extraterrestrial solar irradiance for the two wavebands, corrected for absorption by atmospheric ozone, and \( \varepsilon(\lambda_1, \lambda_2) \) is the ratio of the aerosol optical thicknesses at \( \lambda_2 \) and \( \lambda_1 \). \( \varepsilon \) depends only on the type of aerosol present in the atmosphere and not its concentration. For the ocean a reasonable assumption is that the aerosol type is the same across an image and only the concentration varies. Thus if \( \varepsilon \) can be determined for the pairs of CZCS bands somewhere in an image, then the water-leaving radiances can be calculated for the whole image. This was done based on the clear water radiance concept which gives \( L_w(520), L_w(550) \) and \( L_w(670) \) when the pigment concentration is less than 0.25 mg m\(^{-3}\). This allows \( \varepsilon(520,670) \) and \( \varepsilon(550,670) \) to be determined for pixels satisfying the clear water condition, and \( \varepsilon(443,670) \) is extrapolated from these values. The further assumption
that \( L_w(670) = 0 \) then allows the water-leaving radiance in the other three bands to be determined. This is based on the fact that water absorbs light strongly in the red/near-IR region of the spectrum,\(^{(16,22)}\) which is a reasonable assumption for clear oceanic waters. There are problems with this approach if there is no clear water in the image or if the aerosol type varies across the image. For the first problem, an iterative approach is possible by starting with an initial guess for \( L_w(670) \).\(^{(20,21)}\) The second problem, together with the problems due to the simplifying assumptions made in the CZCS approach, can only be dealt with by a more sophisticated pixel by pixel atmospheric correction procedure, which can incorporate the information available from the extra channels of the new sensors. These are being developed and applied.\(^{(16,22)}\)

The CZCS atmospheric correction procedure worked reasonably well for the open ocean, but less well in coastal areas. It is not valid to make assumptions about the constancy of aerosol type near land, and about the water-leaving radiance in the red/near-IR region when there are sediments in the water.\(^{(11,21)}\) For reasons like these it has proved useful to distinguish between two different water types when using the data from color sensors, as explained in the next section.

### 2.4 Case 1 and Case 2 Waters

Before proceeding further in the discussion of ocean color measurements it is necessary to define the terms Case 1 and Case 2 waters, which are often used in the remote sensing of ocean color. These terms were originally used by Morel and Prieur.\(^{(19)}\) Case 1 waters are ones where the optical signature is due to the presence of phytoplankton and their by-products. Case 2 waters are ones where the optical signature may also be influenced by the presence of suspended sediments, dissolved organic matter and terrigenous particles from rivers and glaciers. In general, Case 1 waters are those of the open ocean, while Case 2 waters are those of the coastal seas. The derivation of geophysical parameters from Case 2 waters is much more complex, as the presence of the various particulates in the water, in addition to the phytoplankton, affects the color signal measured by the satellite sensor.\(^{(12,23)}\) This also makes atmospheric correction of the data more difficult (see section 2.3). Given these complications and that the focus of this article is on biological oceanography, further discussion will be restricted to Case 1 waters. It is worth noting that the new generation of satellite sensors (SeaWiFS, MODIS, MERIS; see next section) which possess more bands in the visible part of the spectrum than did CZCS, will allow better discrimination between the various in-water constituents in Case 2 waters.\(^{(24)}\) Almost all the applications of ocean color data that will be discussed below (section 4) will be from open ocean Case 1 waters.

### 3 SATELLITES AND SENSORS

From the previous section, it is clear that it is necessary to measure the spectral properties of the light leaving the ocean, and to correct for the effects of the intervening atmosphere on the measurements, in order to obtain useful biological measurements from spaceborne sensors. In this section, the characteristics of various ocean color sensors that have been, or will be, flown in space are described. In addition, an overview of the algorithms used to derive biological information will be presented together with an explanation of how these have been calibrated and validated.

#### 3.1 Missions and Sensors Characteristics

As noted in the historical introduction (section 1.1) a number of ocean color sensors have been or are to be flown in space. The characteristics of each sensor will be given in the following subsections. Here a summary of the instruments and satellites is provided in Table 1. (The experimental sensors MOS and OCI mentioned in the historical survey have been excluded from what follows.) Details of earlier visible band sensors that were not specifically designed for ocean color studies but have been used for such may be found in Robinson\(^{(2)}\) and Stewart.\(^{(3)}\)

Optical sensors are essentially of two types, pushbroom or scanning. Pushbroom sensors have optics that enable a line of data, in an across-track direction, to be acquired at the same time. Scanning sensors have optics that scan in the across-track direction, thus acquiring a line of data. The swath width of the sensor is determined by the height above the surface and the maximum angle of view across-track to either side of nadir. The instantaneous field of view (IFOV) of the sensor fixes the size of the pixels that make up each line of data. The angular resolution of the sensor’s optical system and the height of the satellite orbit determine the IFOV. Owing to the viewing geometry, for a fixed angular resolution, this means that pixels at nadir are somewhat smaller than those out towards the edge of the instrument swath. An image is built up of successive

lines of data as the satellite moves along its orbit. Some optical sensors flown in space also have the capability to tilt, thus being able to look ahead or behind the satellite, rather than just down at nadir. This capability is used to avoid sunglint problems over certain parts of the satellite’s orbit, by tilting the sensor away from the sunglint (the direct reflection of the sun in the sea surface). Clearly the degree of tilt will affect both the swath width and the pixel size.

In the following, details of the individual sensors will be given, including the type of sensor (pushbroom or scanning, tilting or nontilting), the orbit height, the swath width, the spatial resolution (pixel size) and, most important, the bands in the electromagnetic spectrum in which each sensor measures. At the typical orbit altitudes and swath widths of the satellites and sensors, respectively, global coverage of the oceans is acquired over about three days (on-board recording capability permitting).

### 3.1.1 Coastal Zone Color Scanner

CZCS was a scanning sensor able to scan ±39.34° each side of nadir. The satellite altitude of 955 km meant that the resulting swath width was 1659 km when the sensor was in nadir-looking mode. The sampling of the scan was such as to give 1968 pixels across the swath. The sensor could tilt ±20°, in steps of 2° to avoid sunglint. The IFOV (ca. 0.05°) gave pixels that varied from 825 m at nadir to 1653 m at the edge of the swath (again in nadir-looking mode). The swath width and pixel size varied with the degree of tilt. The sensor had six channels (Table 2), four in the visible part of the spectrum, one in the near-IR, and one in the thermal IR.\(^{[21,25]}\)

Owing to limitation of power on board the Nimbus-7 satellite, CZCS was limited to only two hours of operation each day. Furthermore, limited data-recording capability meant that much of the data had to be acquired when the satellite was within reception range of a ground recording station. When combined with the problems of cloud cover this meant that, over its lifetime 1978–1986, CZCS data coverage was somewhat patchy. Despite this, it provided the first global view of the biology of the oceans and subsequent work on the data has produced a calibrated and consistent data set for that period.\(^{[6]}\)

Over its period of operation the visible band detectors were found to be suffering from decreasing and variable sensitivity,\(^{[18,15]}\) and careful correction for this effect was necessary in order to make full use of the data.\(^{[9]}\) The broad near-IR band (band 5; see Table 2) was only useful for land–sea–cloud discrimination. In addition, the thermal IR band detector failed shortly after launch so that SST data were not available. Most of the processing effort has therefore focused on data from the four visible bands (bands 1 to 4).\(^{[21]}\)

### 3.1.2 Ocean Color and Temperature Sensor

After a gap of 10 years from the demise of CZCS, OCTS was launched in August 1996. Unfortunately the mission was short lived as the ADEOS satellite suffered a catastrophic failure in June 1997, thus acquiring only nine months of data. Although launched prior to SeaWiFS (which was to have been launched about 1994), OCTS was designed in the light of SeaWiFS and was therefore in some respects a very similar instrument. It had six visible bands and two near-IR bands, which corresponded very closely to the SeaWiFS bands (compare Tables 3 and 5). In addition, OCTS had four bands in the thermal IR (see Table 4) which allowed the retrieval of SST, thus providing contemporaneous information on ocean biology (from color) and physics (from SST). The spatial resolution at nadir was approximately 700 m. The nominal orbit altitude was 700 km, giving a swath width of about 1400 km. The sensor was of the scanning type, with the ability to tilt ±20° forward and backwards to avoid sunglint.\(^{[26]}\)

### 3.1.3 Sea-viewing Wide Field-of-view Sensor

SeaWiFS was designed as the successor to CZCS, but for a variety of reasons its launch was delayed until

August 1997, over 10 years after the demise of CZCS. It is now in orbit and providing very high quality ocean color data. Unlike CZCS, it has no bands in the IR, so provides no information on SST (its successor MODIS will have IR bands, see section 3.1.4). A comparison of the capabilities of CZCS and SeaWiFS is given by Hooker et al. SeaWiFS flies on the SeaStar satellite operated by OSC, with NASA buying the data for distribution to the scientific community, while OSC sell the data to commercial organizations for other applications (see section 4.6).

SeaWiFS has six bands in the visible part of the electromagnetic spectrum and two bands in the near-IR for atmospheric correction purposes. These bands are very similar to those of OCTS (compare Tables 3 and 5). The increased number of visible bands, plus the bands in the near-IR, and the improved sensitivity (see S/N in Tables 2 and 5) will allow better atmospheric correction of the data and improved retrieval of biological information, compared with CZCS. SeaWiFS is a scanning instrument and has the capability to tilt ±20° forwards or backwards to avoid sunglint. It is operated in two spatial-resolution modes, local area coverage (LAC) with a 1.1 km resolution at nadir, and global area coverage (GAC) with a 4.5 km resolution at nadir. At the nominal orbit altitude of 705 km, the LAC has a swath width of 2801 km, while the GAC has a swath width of 1502 km. The on-board recording system has only limited capacity for LAC data, so this capability is primarily for use when the satellite is within range of a ground receiving station.

a NEAT, Noise equivalent temperature difference.

2 have a spatial resolution of 250 m, bands 3–7 of 500 m and bands 8–36 of 1 km. Thus the spatial resolution of the bands being used for biological oceanography (8–16) is similar to that of CZCS, OCTS, and SeaWiFS. The bands are narrower and the sensitivity greater than for the earlier instruments (see Tables 2, 3 and 5). The instrument is of the scanning type and has a swath width of 2330 km at its nominal operational altitude of 705 km, with 1354 pixels across the swath. In order to obtain the best
possible measurements the instrument has four on-board calibration systems (see Barnes et al.\(^9\) for details).

Although it was conceived as a two-instrument system (MODIS-T, with tilt capability, and MODIS-N, nadir looking), owing to cost constraints the tilting capability had to be foregone and a single instrument was designed. In order to compensate for the loss of oceanographic data due to sunglint (which could have been reduced using the tilt mechanism), a second MODIS instrument will be flown on the EOS-PM1 platform. It turns out that it is cheaper to design a single instrument and fly a duplicate, than to design and fly the original two-instrument system. The two instruments together will provide approximately the same global coverage as a single tilting instrument.\(^9\)

The MODIS capabilities for ocean observations are described by ESAi et al.,\(^9\) so only a brief summary is given here. It should be noted that MODIS’s ability to measure SST (using the IR bands), in addition to ocean color, will allow it to provide data on biophysical interactions. The end-result of the improved instrument performance is the ability to obtain more information on ocean biology. Basic information derived will concern the water-leaving radiance in the various bands. From these data information on pigment concentrations, chlorophyll-a, coccolithophores (see section 4.1.3), phycoerythrin (a specific algal pigment), ocean primary production (see section 4.1.2), and solar-stimulated chlorophyll fluorescence will be obtained.\(^9\) MODIS will be the first satellite instrument to provide data on phycoerythrin and solar-stimulated chlorophyll fluorescence (see section 4.7.2).

### 3.1.5 Medium Resolution Imaging Spectrometer

MERIS\(^1\(^1\)\(^0\)\) is the ESA equivalent of NASA’s MODIS instrument described in the previous section, but without the bands in the IR part of the electromagnetic spectrum. It too will provide data for atmospheric and terrestrial, as well as oceanographic, studies (see Table 8). MERIS is a 15-band programmable instrument, so that the band positions and widths can in principle be changed during the mission. Only 15 of the 16 preliminary bands, listed in Table 8, will be acquired and transmitted when MERIS is in orbit. It will fly on ESA’s Envisat satellite at a nominal altitude of 800 km, giving it a swath width of about 1150 km, with 740 pixels across the swath. MERIS is a nontilting pushbroom type of instrument, so it will suffer from sunglint problems similar to MODIS.

MERIS had been designed to be useful for both global and regional studies. For this reason it has two spatial resolution modes. The so-called full-resolution mode has a resolution of 300 m at nadir, while the reduced-resolution mode has a resolution of 1200 m at nadir, the latter being similar to CZCS, OCTS, SeaWiFS, and MODIS. The full-resolution mode is intended for regional studies only, as the on-board data recording capacity is insufficient to capture all the data at this resolution on a global scale. Table 8 gives some indication of the types of information that will be derived from the various MERIS bands (see also Rast\(^1\(^0\)\)). As with MODIS, particular care has been taken with the calibration systems for MERIS to ensure high quality of data.

### 3.2 Algorithms, Including Atmospheric Correction

As noted earlier (section 2), the critical measurement made by an ocean color sensor is the value of the water-leaving radiance \(L_w\) in each band in which the sensor measures. These measurements can then be related to the in-water biological constituents that are of interest to the biological oceanographer. The standard atmospheric correction algorithms used to produce the global CZCS chlorophyll (pigment) concentration data set that is now widely available\(^6\) are given by McClain et al.\(^2\(^9\)\). They are empirical algorithms that take into account the changes in the chlorophyll concentration. Thus the satellite-determined chlorophyll concentration \(C_{\text{sat}}\) is given by Equations (5) and (6).

\[
C_{\text{sat}} = 1.13 \left( \frac{L_w(443)}{L_w(550)} \right)^{-1.71}
\]

for \(0 < C_{\text{sat}} < 1.5 \text{ mg m}^{-3}\) \(\text{ (5)}\)

</table>
The change in algorithm at specific areas (for example, the Southern Ocean).

\[ C_{\text{sat}} = 3.33 \frac{L_w(520)}{L_w(550)}^{-2.44} \]

for \( 1.5 \text{ mg m}^{-3} < C_{\text{sat}} \). (6)

The change in algorithm at \( C_{\text{sat}} = 1.5 \text{ mg m}^{-3} \) is necessary as the value of \( L_w(443) \) becomes too small to quantify accurately at greater concentrations owing to the digitization and signal-to-noise characteristics of CZCS.

The estimation of the near-surface pigment concentration using these algorithms is accurate to within 35% for Case 1 waters. (6)

The above algorithms are based on comparisons of the satellite data with in situ measurements and are therefore empirical in nature. More sophisticated algorithms have been developed for CZCS data that rely on modeling the dependence of the water-leaving radiances on the phytoplankton pigment concentration (for example, the so-called semianalytic model of Gordon et al. (20)). In addition, regional algorithms have been developed to improve the retrieval of chlorophyll concentration in specific areas (for example, the Southern Ocean). (30) These types of algorithm have not been applied routinely to CZCS data. The new generation of ocean color sensors, with more bands and improved digitization and S/N, will allow more sophisticated algorithms to be employed and more, and more accurate, biogeochemical information to be recovered from the data. (9, 24)

In order to obtain the water-leaving radiance values a simple atmospheric correction algorithm has been applied to the CZCS data set. A standard atmospheric aerosol type was assumed in order to correct for the presence of aerosols in the atmosphere. (6) This correction introduces errors in regions where other types of atmospheric aerosol are present, such as off the north-west African coast, which is affected by Saharan dust. Other atmospheric correction algorithms have been developed and used for specific circumstances, some details of which have been given by Barale and Schlittenhardt. (21) More sophisticated algorithms have been designed for the new generation of ocean color sensors (see, for example, Gordon and Wang (22) for SeaWiFS and Gordon (16) for MODIS). All the algorithms used for ocean color data have to screen the data to eliminate sunglint effects, and some of the more sophisticated algorithms take into account other effects that contribute to the radiances measures by the sensor, such as the presence of whitecaps on the sea surface. It is important to note that as the new generation of ocean color sensors have more radiometric sensitivity than CZCS, this in turn requires a better atmospheric correction algorithm if more accurate measurements of water-leaving radiances are to be made. The extra bands that the new sensors have allow for the atmospheric correction procedure to be much improved over that used for CZCS. (16)

The spatial and temporal coverage of the oceans provided by CZCS was patchy. The data have been averaged to provide so-called higher level products, such as weekly and monthly composites. These can be used more easily to study such phenomena as seasonal variations (section 4.1). Thus at Level 1 there are the individual CZCS images, with calibrated radiances, having a spatial resolution of 1 km. At Level 2 there are the derived geophysical parameters for each CZCS images, at a 4 km spatial resolution, the derived parameters being the phytoplankton pigment concentration, the diffuse attenuation coefficient, normalized water-leaving radiances at 440, 520, and 550 nm, and the aerosol radiance at 670 nm. At Level 3, the data have been binned onto an Earth-grid with about an 18.5-km resolution at the equator. The Level 3 data are available as daily, weekly (5 days) and monthly averages. Full details of these data are given by Feldman et al. (9) SeaWiFS and OCTS data are now becoming available in similar formats over the Internet.

### 3.3 Calibration and Validation

The calibration and validation of spaceborne ocean color sensors is vital if the data obtained are to be used in any quantitative manner, rather than just as images of the sea. Considerable effort has been and will continue to be devoted to the calibration and validation of the data from ocean color sensors. Particular emphasis on the quality of the atmospheric correction applied to the data is necessary, as this has such a large impact on the retrieved water-leaving radiances values that provide the basic input into all the bio-optical algorithms. (8) As noted in the previous subsection, if the improved radiometric sensitivity of the new sensors means that a better atmospheric correction be applied to the data, this in turn will need to be validated. (31)

The details of the calibration and validation process are rather involved and so will not be discussed in detail here. There are on-board calibration systems that monitor the performance and stability of the sensor (see, for example, Evans and Gordon (8) for CZCS and Barnes et al. (28) for MODIS). More generally, what are required are accurate measurements of the optical properties of the water and of the atmosphere (particularly with regard to atmospheric aerosols), and of the phytoplankton and associated pigments found in the water. Instruments that can be deployed from both ships and buoys have been developed to make such measurements (see, for example, Clark et al. (31)). In addition, measurements of other contributions to the radiance seen by the satellite sensor, such as that due to whitecaps, need to be made. Even if such measurement techniques are available, care...
must be taken to make measurements across a range of conditions for the calibration and validation process to be successful and useful. A further consideration is the temporal and spatial sampling of the in situ measurements compared with those made by the satellite. Clearly a ship can survey only a small part of an area that the satellite can see instantaneously, and in the time it takes to carry out the survey conditions may have changed (for example, owing to the currents advecting the phytoplankton around). Similarly how representative are data measured by a buoy at a single point, compared with the typical 1-km square pixel measurement obtained by the satellite, given the spatial variability of the phytoplankton?

The end-result of the calibration and validation efforts for the CZCS global data set was that the accuracy of the pigment concentration retrieval was shown to be 35% in Case 1 waters, and within a factor of two otherwise.\(^6\) The aim for SeaWiFS is to obtain water-leaving radiances to within 5% and chlorophyll-a concentration to within 35% across the range 0.05–50 mg m\(^{-3}\).\(^25\) To achieve this a comprehensive calibration and validation plan has been adopted.\(^32\) Similar procedures are being adopted for the other ocean color missions\(^31\) and should provide well-calibrated data for use in scientific studies.

4 APPLICATIONS

The previous sections have given some indication of the complexity of obtaining biological information from remotely sensed ocean color measurements from space. In this section the focus will be on how such measurements may be used to improve our understanding of biological oceanography. All the examples that will be discussed rely on the use of CZCS data. Although OCTS and SeaWiFS have provided and are providing new ocean color data (see section 2), little has yet appeared in the open literature on the application of these data to the study of ocean biology. In addition to scientific applications of the data, which will be the main focus of this section, the commercial applications of the data will also be briefly discussed, as will potential future scientific applications of data from the new generation of ocean color sensors (MODIS, MERIS).

Before proceeding it is useful to define and discuss a number of terms that will be used in this applications sections.\(^5\)\(^,\)\(^13\)\(^,\)\(^17\) The growth of phytoplankton in the upper layers of the ocean is controlled by the availability of sunlight and nutrients (such as nitrate, silicate, phosphate, and iron) and by predation (the algae being eaten by zooplankton). In general, the phytoplankton may be regarded as passively advected by the turbulent flow in the ocean surface layer, the so-called mixed layer. A phytoplankton bloom occurs when the factors affecting growth are such that rapid growth can occur. For example, blooms may be caused by the injection of nutrients into the mixed layer due to the presence of a cyclonic eddy, which causes local upwelling of nutrient-rich water.\(^33\) The spring bloom occurs in certain parts of the ocean (for example the North Atlantic Ocean) when the mixed layer, deepened by the effects of winter storms, begins to shallow as the ocean begins to heat up in the spring (a process known as restratification). The mixing down of the layer in winter has entrained fresh nutrients into the layer. It has also reduced phytoplankton growth as the phytoplankton have been mixed down by the turbulence in the layer away from the euphotic zone. The shallowing of the layer in spring means that the phytoplankton spend more time in the euphotic zone, allowing them to grow rapidly (abundant sunlight and nutrients). At this stage predation is low because zooplankton numbers are low, so phytoplankton growth outstrips zooplankton grazing and a bloom occurs. As the zooplankton begin to grow rapidly and grazing increases, and the phytoplankton use up the nutrients in the mixed layer, growth begins to slow and then the numbers decay owing to mortality and predation. The zooplankton numbers then decrease (owing to lack of food) and by late summer the bloom has finished. This cycle is repeated each year. Various variations of this cycle are possible, but will not be discussed here (see, for example, Mann and Lazier\(^5\) and Longhurst\(^17\)). Regions of the ocean that have low concentrations of the nutrients required for phytoplankton growth are called oligotrophic, while those that have high nutrient concentrations are called eutrophic. Many of the nutrients necessary for phytoplankton growth (such as \(\text{CO}_2\)) are available in the ocean in sufficient quantities not to limit growth. The key nutrients necessary for phytoplankton growth that may only be available in low concentrations, and therefore limit growth, are nitrate, silicate, and phosphate (sometimes called macronutrients). In addition, small quantities of so-called micronutrients (trace elements such as iron) are also necessary for the growth of some species of phytoplankton. Ocean areas where phytoplankton growth is limited by lack of iron or some other process (such as grazing by zooplankton), but that have an abundance of the macronutrients are called high nitrate (or nutrient) low chlorophyll (HNLC) areas.

4.1 Measurements of Phytoplankton

As noted in the introduction, the primary component of the biology about which information is obtained from measurements of ocean color is phytoplankton. In this subsection three particular applications of ocean color relating to phytoplankton directly will be considered: measurement of chlorophyll and related pigments, of
primary production, and of coccolithophores (a particular type of phytoplankton). The examples discussed are illustrative rather than comprehensive; other information may be found in the reviews of Abbott and Chelton \(^{(34)}\) and Aiken et al.\(^{(24)}\)

### 4.1.1 Chlorophyll and Other Pigments

As discussed earlier (section 2) ocean color measurements give information about the phytoplankton present in the near-surface layers of the ocean due to the presence of chlorophyll-a and other pigments necessary for photosynthesis in the phytoplankton and to associated colored degradation products from the phytoplankton. Thus the basic information provided from the ocean color sensor is a measure of the surface concentration of chlorophyll-a and associated pigments. Relating this concentration to the phytoplankton is a nontrivial exercise,\(^{(11)}\) but the satellite chlorophyll concentration measurements in themselves have provided a unique insight into the global biological behavior of the oceans.

Perhaps the simplest observation that has been made has arisen from producing seasonal (spring, summer, autumn, winter) pictures of the global chlorophyll concentrations derived from CZCS data (see, for example, McClain et al.\(^{(29)}\) and Figure 1). These pictures show: (1) the occurrence of the spring bloom in the North Atlantic, (2) the relatively constant biological behavior of the Southern Ocean, (3) the low-concentration (desert-like) regions of the subtropical gyres, (4) the high concentrations in the Arabian Sea during the summer monsoon, and (5) the higher concentrations in the northern and tropical Atlantic compared with equivalent regions of the Pacific Ocean. The reasons for these phenomena are related to the ocean physics and will be discussed below (section 4.3). The point to note here is that, while these phenomena had been observed previously from scattered ship-based observations, CZCS data on chlorophyll concentrations provided the first global and spatially coherent view of them.

Yoder et al.\(^{(35)}\) have used the monthly CZCS chlorophyll concentration values to look at the biological seasonal cycle in the oceans on a global scale. They averaged the data spatial into latitude bands, defining an equatorial band and northern and southern hemisphere subtropical and subpolar bands. Despite some problems associated with the coverage available from CZCS data, fewer data having been acquired in the southern hemisphere than in the northern, they were able to compare the seasonal changes in the chlorophyll concentration for the Atlantic, Pacific, and Indian Oceans in the appropriate latitude bands. They found that the coverage of the equatorial Atlantic Ocean was poor and concluded that the annual cycle, with a maximum in December, may not be representative. For the equatorial Pacific Ocean they found no seasonal cycle, while for the equatorial Indian Ocean they concluded that the maximum in August/September is related to the subtropical monsoon cycle there. For the subtropical Atlantic and Pacific Oceans, they found that the seasonal cycles are similar, with the winter chlorophyll concentrations approximately double those of the summer. This pattern was attributed to the higher nutrient flux into the mixed layer in winter and the relatively high solar irradiance during winter (compared with higher latitudes). The subtropical northern Indian Ocean was found to be anomalous, with the highest chlorophyll concentrations in the summer months. This was explained by the upwelling of nutrient-rich waters during the summer monsoon. For the subpolar waters of the North Pacific and North Atlantic Oceans they found the existence of the spring bloom, which was more pronounced in the North Atlantic Ocean. This bloom is the result of the increase in solar irradiance in the spring, the shallowing of the mixed layer (due to solar heating and restratification) and the corresponding growth in phytoplankton. This growth outstrips the zooplankton grazing rate initially, but by late spring or summer the phytoplankton losses are greater than their growth and the bloom declines. The subpolar waters of the southern hemisphere were found not to exhibit this pattern. This hemispherical asymmetry may be due to differences in micronutrient (iron) availability, solar irradiance, vertical mixing, or zooplankton grazing. Overall, the seasonal patterns found by Yoder et al.\(^{(35)}\) are consistent with predictions based on simple models of predator–prey (zooplankton–phytoplankton) interactions with implicit assumptions about growth limitation by nutrients and solar irradiance. In some respects this agreement is surprising as there is considerable spatial and temporal variability in the distribution of phytoplankton (section 4.3). Therefore the averaging procedure used\(^{(35)}\) might have suppressed or distorted any seasonal signal, which it has not. Instead, their results confirm on the large scale a picture of the seasonal behavior of the phytoplankton that was arrived at originally from a more limited set of in situ observations. Banse and English\(^{(36)}\) have given a complementary view of seasonal cycles which focuses more on specific areas and considers interannual variability. Their results are in broad agreement with those of Yoder et al.\(^{(35)}\) but show more regional detail as they did not use latitudinal averaging.

Moving from the global to a more regional scale, Sullivan et al.\(^{(30)}\) have studied the distribution of phytoplankton blooms in the Southern Ocean (south of 30°S) using CZCS data, a region poorly sampled by traditional ship-based measurements. They derived a regional pigment retrieval algorithm to improve the estimation of chlorophyll concentration from the CZCS data.
Figure 1 (a) CZCS seasonal sea surface chlorophyll distribution for the northern hemisphere winter months, using data from 1979 to 1986. Note that the color scale is logarithmic in chlorophyll (phytoplankton pigment) concentration (units of mg chlorophyll m$^{-3}$). Data provided by NASA/Goddard Space Flight Center. (b) As for (a) but for northern hemisphere spring. (c) As for (a) but for northern hemisphere summer. (d) As for (a) but for northern hemisphere autumn. Note the following features of the data shown in the figure: (i) the bloom of phytoplankton (yellow/orange/red) in the North Atlantic Ocean during the northern hemisphere spring, (ii) the bloom of phytoplankton (yellow/orange/red) in the Arabian Sea during the summer monsoon, (iii) the “desert” regions, low phytoplankton (purple), in the subtropical gyres, (iv) black indicates missing data. Even using data from 1979 to 1986 gaps exist in the CZCS data record (see section 3.1.1), (v) the data are illustrative of results discussed in sections 4.1.1 and 4.3.1.
They found that blooms were localized to three regions: (1) in shallower waters (near continental margins, islands, and over shoals), (2) in coastal polynyas of the Antarctic sea ice zone, and (3) downstream of the continents (South America, Africa, Australia plus New Zealand) that interrupt the flow of the major circumpolar currents. In relation to the blooms downstream of the continents, they conclude that transport of iron (thought to be the limiting micronutrient in the Southern Ocean) from the adjacent continental shelves stimulates and sustains these blooms. They provide evidence of latitudinal banding of the chlorophyll concentration around the Antarctic continent and link this to the physical processes that occur there. The results obtained are now being used in conjunction with other observations to study the ecology of the Southern Ocean. This shows that the CZCS data are both of intrinsic interest and of value in gaining a better understanding of the ecology of the oceans, in combination with other data. This points the way forward for the use of the new ocean color data that are being and that will be acquired.

Many other examples of the use of chlorophyll concentration data from CZCS could be given; the ones given have been chosen to illustrate the unique value of remotely sensed ocean color data and their potential for understanding the biology of the oceans.

4.1.2 Primary Production

Phytoplankton are the main primary producers of the upper ocean, in that they convert inorganic compounds (nutrients, such as nitrate and silicate) into organic compounds through photosynthesis. This is the beginning of the oceanic food chain and the amount of organic material (biomass) produced is known as the primary production. The rate at which biomass is produced is known as the primary productivity. The net primary production takes into account losses due to respiration and is the amount of photosynthetically fixed carbon available to the next level in the food chain. The primary production may further be subdivided into new and regenerated components. New production is that based on new nutrients that have entered the euphotic zone, while regenerated production is that which occurs due to the recycling of nutrients there (through processes such as microbial breakdown of dead organic matter and fecal pellets). The ratio of new to total primary production is known as the f-ratio. Understanding the oceanic primary production is important for the carbon cycle and the CO₂ problem (see section 4.2). It is also important in terms of assessing the sustainability of the global fisheries, an increasingly vital issue given the increasing world population’s requirements for food.

In order to estimate primary production it is necessary to have not only the surface chlorophyll information from ocean color data, but also information about the photosynthesis–light relationship and possibly the structure of the chlorophyll distribution in the vertical. Here two recent attempts to estimate the primary production of the oceans from CZCS data are described, those of Longhurst et al. and Field et al. References to earlier attempts may be found in these papers.

Longhurst et al. use chlorophyll estimates from CZCS and an approach developed by Platt and Sathyendranath to calculate primary production. They divide the ocean up into a number of biogeochemical provinces, based on in situ and satellite data, in order to specify the spatial and temporal variability of the parameters that are needed by their algorithm for primary production. The provinces are an attempt to characterize the biological, chemical, and physical variability of the oceans. As well as the surface chlorophyll value from CZCS, their algorithm requires information about the depth of the chlorophyll maximum, the standard deviation around the peak value, and the ratio of the chlorophyll peak at its maximum to the total peak biomass. The latter information is compiled from an extensive database of ship-based observations. From this information a vertical chlorophyll profile is constructed at each point on a global 1° grid on a quarterly basis (centered on the 15th day of January, April, July, and October). The calculations were restricted to a quarterly basis owing to the sparsity of in situ measurements available. Surface radiation was computed from the sun angle and climatological information from cloud cover. This was combined with experimentally derived information on the photosynthesis–light relationship, representing polar, westerlies, trade-wind, and coastal domains, to calculate the total primary production. The calculation makes no allowance for the presence of suspended sediments in coastal waters for which the CZCS chlorophyll algorithm is inadequate and which will affect the estimates obtained. Taking this and other uncertainties into account and integrating over the year, Longhurst et al. estimate the annual primary production as 44.7–50.24 Gt C per year (1 Gt C is one Gigatonne of carbon = 1 Pg C, one Petagram of carbon = 10¹⁵ g of carbon). They found that this figure is in reasonable agreement with extrapolations based on a few good in situ measurements.

Field et al. calculated the net primary production for both oceanic and terrestrial biospheres. For the ocean they used a depth integrated model, which requires information about the surface chlorophyll concentration, the depth of the euphotic zone, PAR, and a temperature-dependent maximum chlorophyll-specific carbon fixation rate (the amount of biomass measured in carbon per unit chlorophyll per day). The temperature field is also obtained from satellite data (from AVHRR), as is the solar irradiance (from Bishop and Rossow).
This model is based on the work of Behrenfeld and Falkowski, who suggest that the improvement gained by using a vertically resolved model, such as that of Longhurst et al., is negligible compared with using a depth-integrated model. Their resulting estimate of global net primary production is 48.5 Gt C per year, which lies in the middle of the range calculated by Longhurst et al. It is interesting to note that while the production is of the order of 50 Gt C per year, the actual phytoplankton biomass is only ca. 1 Gt C. This implies that the phytoplankton biomass turns over approximately once per week on average. This is consistent with the fact that the phytoplankton lifecycle is relatively short, of the order of a day.

Prior to the availability of ocean color data, estimates of global primary production were more difficult to obtain. Both of the approaches discussed above rely on more than just the satellite data to obtain these estimates. Neither method is able to distinguish between new and regenerated production, which it is necessary to do in studying carbon fluxes into the ocean (section 4.2). However, Sathyendranath et al. have proposed a method for doing this using satellite data (see section 4.2 below). Algorithms for estimating primary production are being developed for MODIS.

4.1.3 Coccolithophores

Coccolithophores are phytoplankton that form external calcium carbonate CaCO₃ scales called coccoliths, which are a few micrometers in diameter and ca. 250–750 nm in thickness. These can form multiple layers, which eventually detach and sink to the sea floor. Coccolithophores are also one of the principal producers of dimethyl sulfide (DMS). Their importance is probably greatest during a bloom, where their concentrations can reach up to 115 million cells per liter. The most abundant of the species is Emiliania huxleyi, which can be found throughout most of the world’s oceans, with the exception of the polar oceans. They can be detected in satellite imagery because the presence of the coccoliths leads to high reflectance in the surface waters due to their intense scattering of light. Essentially they act like small mirrors suspended in the water and cause a significant portion of the incoming light to be reflected back out from the water.

Whereas phytoplankton pigments change the water-leaving radiance differential across the spectrum owing to absorption, coccolithophore blooms tend to increase the radiance uniformly owing to scattering. The resulting appearance of the ocean can be milky, which is how these blooms were first observed by eye. A consequence of this is that coccolithophore blooms can be detected using the visible channels of the AVHRR, which are not sensitive enough for studying other changes in ocean color. Another consequence is that, in the case of ocean color sensors, a different algorithm needs to be used to estimate their abundance from satellite data. It also means that it is possible to monitor one specific species of phytoplankton, whereas the standard chlorophyll measurements obtained from ocean color do not allow discrimination between different species of phytoplankton. Two effects of the presence of large numbers of coccoliths in the water are first, an increase in the ocean’s albedo, and, second, a shading effect that reduces the light level in deeper water (while the scattering of photons increases the light level in the surface waters). These effects have not been studied using satellite data to date (1999).

The most comprehensive study of coccolithophore blooms in the global ocean using ocean color data, from CZCS, is that of Brown and Yoder. They mapped the distribution of blooms using CZCS five-day composite normalized water-leaving radiance data from 1978 to 1986. The data used have a spatial resolution of 20 km. An automatic spectral classification scheme was used to detect the blooms, based on the spectral characteristics that have been obtained from in situ measurements. Monthly and annual composites were calculated from the five-day composite analyses. They found that coccolithophore blooms annually covered an average area of 1.4 × 10⁶ km² of the global ocean from 1979 to 1985. This represents ca. 0.5% of the ocean surface. Blooms were most extensive in the subarctic North Atlantic Ocean, annually covering an area of 10⁵ km² (approximately equivalent to the size of England). As the scattering of light is due to the presence of coccoliths in the water, rather than of the cells themselves, the results are biased towards the declining stage of the blooms when the proportion of coccoliths to cells is greatest. Based on these results they were able to make estimates of CaCO₃ and DMS production, using further assumptions regarding the depth of the mixed layer and the concentrations of cells and related chemicals within it. They concluded that on a regional scale the blooms are a significant source of CaCO₃ and DMS. In contrast, on a global scale, the blooms detected in CZCS imagery play only a minor role in the production of CaCO₃ and DMS and their flux from the mixed layer to deeper waters and to the atmosphere, respectively.

4.2 The CO₂ Problem

Phytoplankton live in the surface sunlit waters of the ocean. When they grow and reproduce, they absorb carbon dioxide and other chemicals (nutrients) from the water. When phytoplankton blooms occur, the surface waters become depleted in CO₂. This induces an
imbalance between the atmosphere and ocean that allows the ocean to absorb CO$_2$ from the atmosphere. Most of the CO$_2$ removal is not permanent. Approximately 90% of the phytoplankton die and are decomposed in the surface waters rereleasing their CO$_2$. The remaining fraction (ca. 10%) sinks down into the deeper ocean where it remains out of contact with the atmosphere for long periods of time (as much as 1000 years). A very small fraction ($\leq$1%) reaches the sea floor where it becomes part of the sea floor sediments and is therefore totally removed from the system (on timescales shorter than geological ones, that is millions of years).\(^{49}\) Ocean color measurements have been used to look at two parts of this process, the transfer of gases between atmosphere and ocean, and the so-called biological pump that removes the CO$_2$ to the deep ocean and sediments.

### 4.2.1 Air–Sea Gas Transfer

The air–sea transfer of gases is dependent on many complex processes including wave breaking, the production of droplets and spray, the entrainment of air bubbles into the water and their subsequent behavior, and the presence or absence of surfactants. Clearly this complexity is too difficult to model in all its aspects. Therefore the net air–sea flux of CO$_2$ is usually parameterized in terms of a wind speed-dependent gas exchange coefficient multiplied by the difference in the partial pressure of CO$_2$ ($p$CO$_2$) in the air and in the water.\(^{50}\) The presence of phytoplankton in the surface waters of the ocean, which use the CO$_2$ for photosynthesis, decreases the $p$CO$_2$ of the surface waters allowing greater uptake of CO$_2$ from the atmosphere. At the present time the potential feedback (whether positive or negative) between changes in climate (increasing atmospheric CO$_2$) and the phytoplankton are not understood.\(^{41}\)

In situ measurements in the North Atlantic Ocean\(^{51}\) have shown that the spatial variability of the oceanic $p$CO$_2$ is correlated with the spatial variability of the SST and chlorophyll concentration. These results were obtained in the springtime, during the bloom period. Watson et al.\(^{51}\) suggest that using satellite-derived SST and chlorophyll values may allow the determination of the $p$CO$_2$ value. Subsequent modeling studies by Antoine and Morel\(^{52}\) (see also Antoine and Morel\(^{53}\)) have shown that the relationship between $p$CO$_2$, SST, and chlorophyll varies spatially and temporally, but may be sufficiently stable on a seasonal basis to make a $p$CO$_2$ estimate based on satellite data. To date (1999) this does not appear to have been done.

However, a related study has been carried out by Erickson and Eaton\(^{54}\) who studied the flux of carbonyl sulfide from ocean to atmosphere, using CZCS data and an ocean general circulation model. The CZCS chlorophyll data are related empirically to the maximum potential carbonyl sulfide concentration in the surface ocean. The assumption is that the chlorophyll data are representative of the maximum supply of organosulfur compounds that are available for photooxidation. The maximum potential concentration is then related to the actual concentration taking account of the surface radiation field of the ocean. Using an appropriate gas transfer coefficient (see above and Liss and Merlivat\(^{55}\)) and information on surface radiation, the wind field, and SST, Erickson and Eaton\(^{54}\) calculate the gas flux for a five-year period, with a 2.8° spatial resolution, and a 24-hour temporal resolution. Computed values of surface concentrations of carbonyl sulfide are said to agree with experimental data on a regional basis to within the uncertainties of the calculation. They found two orders of magnitude variation in the spatial and temporal gas flux, with the comment that the technique is potentially extendible to other biogeochemically important gases, such as CO$_2$.

To conclude this section, it is worth noting that the gas transfer coefficient itself may be estimated from satellite scatterometer or passive microwave radiometer data on the oceanic wind field. Etcheto et al.\(^{56}\) have used passive microwave radiometer wind speed data and the Liss and Merlivat\(^{55}\) formulation of the transfer coefficient’s dependence on wind speed to do this. They show that the seasonal variations are large and need to accounted for in calculating the flux of CO$_2$. Together with satellite-based SST and chlorophyll measurements, this provides the basis for global calculation of the air–sea flux of CO$_2$ and other biogeochemically important gases.

### 4.2.2 Biological Pump

The biological pump refers to the process by which part of the of the primary production is removed from the surface layers of the ocean to the ocean interior, as sinking organic particles and as dissolved organic matter. Thus the biological pump reduces the carbon in the surface layers of the ocean (and consequently the CO$_2$ in the atmosphere) and increases the carbon content of the ocean interior, a small fraction of which becomes sediment on the ocean floor.\(^{1}\) If the processes controlling the primary production were in a steady state, the export production (that part of the primary production lost from the surface layers) would be equal to the new production due to nutrients entering the upper layers of the ocean (section 4.1.2). Thus knowledge of the $f$-ratio (new-to-total production) should give some information about the behavior of the biological pump.\(^{57}\) The estimation of the $f$-ratio, or equivalently the new and total production, from satellite data has been carried out by Sathyendranath et al.\(^{45}\) for the Georges Bank area. Using AVHRR SST data, they derived the $f$-ratio using relationships
between temperature, nitrate, and the f-ratio based on in situ measurements. Combining this with estimates of primary production from CZCS data, they were able to estimate new production. Such an approach may provide information on the biological pump, but the assumption that the processes controlling primary production may be regarded as in a steady state has been questioned.\footnote{\textsuperscript{44}} Storms, eddies, El Niño, and other transient physical processes affect the delivery of nutrients to the ocean's surface layers (see section 4.3). On short timescales (up to interannual ones) a steady state cannot be assumed. Over longer timescales an approximate steady-state situation may exist. The processes involved are too complex to be understood using only limited observations (such as SST and ocean color from satellites and some in situ data) and the best way to study them is probably through combining the observations with biophysical models (see section 4.4). Empirical algorithms for estimating new, export, and primary production are being developed for use with MODIS.\footnote{\textsuperscript{9}}

### 4.3 Biophysical Interactions

It is well known that the biology in the oceans is influenced by the physical and chemical processes occurring there.\footnote{\textsuperscript{5,\textsuperscript{17}}} These processes occur across the whole range of time- and space-scales present in the ocean, therefore biological distributions in the sea are patchy on a variety of spatial and temporal scales.\footnote{\textsuperscript{58}} This patchiness results from interactions between physical and biological factors with the dominating forcing functions changing with scale. Physical circulation dominates basin scale variability and sets the overall context within which biological distributions are correlated to water masses. At the mesoscale, variability is dominated by fronts and eddies\footnote{\textsuperscript{59,\textsuperscript{60}}} and at scales below this, variability becomes a function of biological behavior interacting with physical processes such as turbulence and mixing.\footnote{\textsuperscript{61,\textsuperscript{62}}} Clearly it is not possible to study the microscale processes, involving turbulence and mixing, with a satellite sensor that has a spatial resolution of ca. 1 km. However, it has proved possible to gain insight into the large scale (gyre scale, O(1000 km)) and mesoscale processes (O(10–200 km)) and these are discussed in the next two subsections.

#### 4.3.1 Large Scale

The links between the large-scale O(1000 km) physical structure of the ocean and its biology has been understood for some time on the basis of in situ measurements made from ships and by using simple models (see, for example, Sverdrup\footnote{\textsuperscript{63}} and Mann and Lazier\footnote{\textsuperscript{5}}). However, as noted by Longhurst,\footnote{\textsuperscript{17}} the distribution of phytoplankton in the ocean was only known in broad terms, while CZCS ocean color data revealed novel information about the global seasonal distribution (see section 4.1.1), despite the fact that CZCS could not directly detect the presence of deep chlorophyll maxima. The basic latitudinal variation in phytoplankton production is due to the decrease in light available for photosynthesis from the equator to the poles and the (inverse) increase in wind mixing which brings nutrients into the surface layers. Both these effects vary seasonally. The ability of the wind mixing to bring nutrients into the surface waters is affected by the degree of stratification (variation of the density gradient with depth) of the ocean. Superimposed on this rather simple picture are the effects of the large-scale ocean currents and gyre circulations, which modify the basic latitudinal variations (Figure 1; see Mann and Lazier\footnote{\textsuperscript{5}} and Longhurst\footnote{\textsuperscript{17}} for more detail).

A description of the physical effects leading to the spring bloom in the North Atlantic (north of ca. 40°N) has been given above (see the beginning of the section), and this bloom has been observed in CZCS data.\footnote{\textsuperscript{17,\textsuperscript{29}}} It has proved possible to relate the northward progression of the bloom during the spring and summer, as observed in CZCS data, to the latitudinal decrease in the mixed layer depth and increase in light levels over that part of the year.\footnote{\textsuperscript{21}} The North Atlantic Ocean is anomalous in having such a strong spring bloom feature.\footnote{\textsuperscript{17}} To the south, the subtropical gyre of the North Atlantic Ocean is oligotrophic, with low levels of phytoplankton, owing to the basic downwellling nature of the flow in the center of the gyre which prevents the supply of new nutrients to the surface layers. This is true of the central gyres of all the oceans, as can be seen from the paper by Falkowski et al.\footnote{\textsuperscript{44}} (see also Barale and Schlittenhardt\footnote{\textsuperscript{21}}), who show the seasonal variation of upper ocean chlorophyll concentrations, from CZCS, alongside the large-scale flow derived from satellite altimeter data. These are the so-called “desert” regions in terms of phytoplankton productivity. It can be seen from CZCS data that there are other regions of the ocean that are more productive, but not as much as might be expected. These are the subarctic eastern Pacific Ocean, the eastern equatorial Pacific Ocean and the Southern Ocean. Despite physical processes that supply sufficient macronutrients for high levels of primary production to occur (as is the case in the North Atlantic Ocean), they appear to be limited by the lack of iron (or grazing by zooplankton; see Mann and Lazier\footnote{\textsuperscript{5}} and Falkowski et al.\footnote{\textsuperscript{44}}). These are the HNLC areas of the ocean.

A specific example of the effect of the large-scale ocean physics on the biology is that of the El Niño in the equatorial Pacific.\footnote{\textsuperscript{64}} This has been studied using CZCS data and a model by Halpern and Feldman.\footnote{\textsuperscript{65}} For non-El Niño conditions they found results consistent with the HNLC scenario. They were able to observe a
reduction in phytoplankton pigment concentration during
the 1982–1983 El Niño due to the smaller nitrate flux into
the mixed layer, this being the result of the reduction of
the upwelling of nutrient-rich waters when El Niño occurs.
It was shown that the amplitude of the annual cycle of
pigment concentration was small (almost undetectable),
whereas the impact of the El Niño (an interannual
variation) was substantial. Owing to the sparsity of CZCS
data for the region in 1983–1984 they were unable to
examine the effect on the biology of the La Niña event that
one of the strongest on record, has been observed by
SeaWiFS and this will no doubt in time provide new
insights into the impact of the event on the ocean biology.
The growth in computing power since 1990 has meant
that more realistic modeling of the physics of the ocean
has been possible and also the development of basin-
scale coupled biophysical models. Using such models
it is possible to predict the overall seasonal changes
in the phytoplankton in the ocean. CZCS data have
provided the means to check whether these predictions
are valid on temporal and spatial scales that would not
be possible using traditional ship-based measurements.
One example is the work of Sarmiento et al. who
modeled the North Atlantic (20°S to 60°N) and found
that their predictions of the seasonal variations in the
surface chlorophyll concentration matched well overall
except for some specific regions. For example, the model
predicted higher concentrations of chlorophyll along the
equator because the model physics leads to too much
nutrient being supplied, allowing more phytoplankton
growth than is observed. The Sarmiento et al. model
did not have the spatial resolution to account for the
effects of eddies, which more recent modeling has been
able to do. Mesoscale features, such as eddies, can play
an important role in the development of the biology and
these will be considered next.

4.3.2 Mesoscale

For the purposes of this discussion the mesoscale is
defined as spatial scales in the range O(10–200 km).
This scale includes such phenomena as eddies, rings,
and fronts in the ocean. One effect of the physics on
the biology is through horizontal advection, where the
currents move the phytoplankton around, and in some
situations trap the phytoplankton in discrete patches of
water such as a ring or eddy. Another effect is that of
the vertical velocities associated with eddies, rings, and
fronts. Upward velocities can bring more nutrients into
the euphotic zone, allowing the phytoplankton to grow.
Downward velocities can move the phytoplankton out of
the euphotic zone thus slowing their growth. A secondary
effect may be through the influence of the horizontal and
vertical currents on the swimming zooplankton that graze
the phytoplankton. As numerous studies of mesoscale
effects exist (see the review by Abbott and Chelton),
only a few examples will be discussed here.

The first example to be considered is that of warm
core rings off the east coast of the USA (see Figure 2).
These rings form when Gulf Stream meanders are pinched
off and trap the warmer Gulf Stream waters in a ring
(or eddy). These rings are typically of O(100 km) in
diameter. Brown et al. describe observations of one
such ring using CZCS data and SST data from AVHRR.
These observations showed that the ring and the Gulf
Stream waters, which were warmer than the surrounding
waters, had lower concentrations of pigment during a
period when a phytoplankton bloom occurred. Garcia-
Moliner and Yoder have carried out a more detailed
study of pigment concentration in warm core rings in the
same region, again using CZCS and AVHRR data. The
correspondence between the SST from the AVHRR and
the pigment concentration can be seen in the images
in their paper. Examining four rings in detail they
found that there is decreasing pigment concentration
with increasing temperature. They examined a number
of hypotheses about the physical processes occurring that
affect the biological structure of the ring and conclude
that advective entrainment of the surrounding waters at
the periphery of the ring is the main factor leading to
variability in the pigment concentration. Considerable
effort has been devoted to the study of ring processes (see
references in Garcia-Moliner and Yoder and Olson)
and ocean color data have contributed to these. Weeks
and Shillington looked at CZCS imagery around South
Africa and showed an image where the Agulhas current
and the rings that spin off from it have lower chlorophyll
concentration than the surrounding waters. They found
an area of high chlorophyll concentration along the east
coast of South Africa, in the Benguela upwelling, which
brings nutrient-rich waters up to the surface allowing
phytoplankton growth to occur.

An area that has been studied in great detail using
CZCS data is the California Current system off the west
coast of the USA. Denman and Abbott have studied
SST from AVHRR and ocean color from CZCS for
the area. They used cross-spectrum analysis to look at the
timescales of the evolution of the mesoscale features
(particularly upwelling jets and the dynamically less active
regions between). They concluded that the patterns of
pigment concentration, which they observed in the CZCS
data, are controlled by the two-dimensional horizontal
mesoscale current field of the upper ocean. They
restricted their analysis to horizontal length scales greater
than 25 km, and noted that for shorter length scales,
biological processes (phytoplankton growth, mortality,
sinking, and predation by zooplankton) may be important
**Figure 2** CZCS sea surface chlorophyll (units of mg chlorophyll m$^{-3}$) image of the east coast of the USA. Clearly visible is the lower productivity water (blue) associated with the warmer waters of the Gulf Stream and with warm core rings shed by the Gulf Stream. The cooler nutrient-rich shelf waters, inshore of the Gulf Stream, show higher productivity (yellow/orange/red). Grey areas denote missing data (primarily due to cloud cover). A variety of mesoscale features – rings, eddies, fronts – can be seen in the image, showing the importance of biophysical interactions for biological productivity. This image is illustrative of the results discussed in section 4.3.2. Data provided by NASA/Goddard Space Flight Center.

for the patterns of patchiness found in the pigment concentrations.

Another example of mesoscale interactions are the filament structures observed in the Portuguese upwelling region by Sousa and Bricaud.\(^{71}\) The upwelling is driven by local winds and occurs in the period late June to October. CZCS images for the region showed no significant patterns in winter and spring, but during the upwelling period filaments of high chlorophyll concentration were found to extend up to 200 km off the Portuguese coast. These filaments are related to topographic features, which affect the currents flowing in the region of the Portuguese coast. Sousa and Bricaud\(^{71}\) also examined the relationship between SST and chlorophyll concentration and found variations consistent with the hypothesis that this relationship depended on the stage of the local upwelling event. The scenario was that initially the upwelled cold nutrient-rich water would have low chlorophyll concentration. This water would be advected offshore while the phytoplankton were growing and SST was increasing. The chlorophyll concentration would then decline as the nutrients were exhausted. Similar behavior had previously been observed off the Californian coast.\(^{72}\) Upwelling regions are known to be highly productive, owing to the supply of nutrients from the deeper waters and are therefore of considerable biological interest.

A secondary application of ocean color data is that of using the biology to infer dynamical information. This has proved useful in a number of situations, a particular example being the case where, because solar heating of the near surface layer leads to uniform ocean surface temperatures, the SST signal of ocean features has not been visible in the IR satellite data. As the color signal (if it exists) is unaffected by such an effect then dynamical structures, such as eddies, can still be detected despite
their lack of a SST signature. Thompson and Gower\textsuperscript{(73)} give an example of an eddy near Vancouver Island that was detected by its CZCS ocean color signal, but could not be seen in the IR AVHRR image. Another approach to obtaining dynamical information from ocean color images is that of feature tracking using successive images (see, for example, Garcia and Robinson\textsuperscript{(74)}). The implicit assumption behind this approach is that the quantity being measured that defines the feature, in this case ocean color, acts as a passive tracer that is simply advected by the ocean currents. As the ocean color is a function of the phytoplankton in the surface waters, a quantity that can be changing rapidly, this assumption is only true on short timescales. Therefore this means of obtaining dynamical information has not been used very much.

4.3.3 Influence of Biology on the Physics

In the previous two subsections the influence of ocean physics on the ocean biology has been considered in detail as this is the primary biophysical interaction. However, a secondary interaction is the effect of the presence of phytoplankton on the solar heating of the surface layers of the ocean.\textsuperscript{(75,76)} The presence of phytoplankton can affect the absorption of solar irradiance by the ocean in different way, depending on their concentration and distribution with depth. Ocean color data from CZCS have been used to study this effect for the equatorial Pacific Ocean.\textsuperscript{(77)} Lewis et al.\textsuperscript{(77)} conclude that some of the discrepancies between observed and modeled SSTs for the equatorial Pacific Ocean may be due to the neglect of penetrating solar irradiance in the models. In order to allow for this effect it is necessary to include biology as well as physics in the models. Some recent coupled biophysical models (for example, that of Oschlies and Garcon\textsuperscript{(66)} for the North Atlantic Ocean) take account of this effect.

4.4 Assimilation of Data into Models

For many and various reasons, perhaps most importantly understanding the role of the oceans in the carbon cycle and the influence of anthropogenic CO\textsubscript{2} emissions into the atmosphere on that cycle,\textsuperscript{(80)} considerable interest exists in developing robust oceanic ecosystem models.\textsuperscript{(78)} By coupling these biological models to physical models of the ocean circulation, the aim is to provide a description, and possibly a prediction, of the contribution of the ocean to global biogeochemical cycles, such as the carbon cycle.\textsuperscript{(79,80)} Another application of the models would be to understand the behavior of the oceanic food chain better, including fisheries.\textsuperscript{(81)}

In attempting to carry this out two problems become apparent. First, in contrast to the modeling of the atmosphere or ocean, where a basic description of the physics is provided by the Navier–Stokes equations of fluid dynamics,\textsuperscript{(82)} there is no basic set of equations that describe the ocean ecosystem. Therefore a heuristic approach is generally taken, where sufficient biological components are modeled to describe the problem of interest.\textsuperscript{(78)} For example, a simple three-component (also called a three-compartment) oceanic ecosystem model might include phytoplankton, zooplankton, and nutrients and has been used with a degree of success for some studies.\textsuperscript{(83)} The second problem is related to the first, in that such heuristic models have many parameters that are known to varying degrees of accuracy (for example, the seven-compartment model of Fasham et al.\textsuperscript{(84)} has 27 parameters). This limits the potential applicability of the models, unless the parameters can be better determined. This provides an ideal application for data assimilation in its guise of fitting models to data.\textsuperscript{(85)}

Another purpose of data assimilation is that of improving the predictive power of models. This is a familiar application in the context of meteorological forecasting. It is also beginning to be used more widely in the area of physical ocean modeling, but is in its infancy with regard to assimilation of data into biological models. Many techniques have been developed for the assimilation of data into models of atmosphere and ocean physics.\textsuperscript{(86,87)} The applicability of these techniques to oceanic ecosystem models is by no mean automatic and much work remains to be done in this area.

As has been made clear thus far, data assimilation is useful for improving both descriptive and predictive powers of models. However, for this to be possible it is necessary to have good measurements of the biology to assimilate into the ecosystem model. Such measurements exist at a limited number of sites (such as Bermuda),\textsuperscript{(88)} or for particular experiments (such as the North Atlantic Bloom Experiment – NABE),\textsuperscript{(89)} but these may not be representative of what is happening in the ocean basin or on the global scale. The availability of ocean color data from OCTS and from SeaWiFS provides measurements that might help in studying these larger scales. The limitation is that only one component (phytoplankton) of the ecosystem is measured, but in combination with a number of in situ measurements that might be sufficient to improve the models, through data assimilation.

The first person to assimilate data into a coupled biophysical model appears to have been Ishizaka,\textsuperscript{(90)} for the southeastern USA continental shelf area. The data assimilated came from CZCS and the assimilation was of the predictive type. The model was a four-compartment ecosystem model (nutrient, phytoplankton, zooplankton, detritus), vertically integrated with horizontal advection and eddy diffusion, but with a semiempirical upwelling/downwelling term added.\textsuperscript{(91)} The coupling to the physics is through the advective velocities, which
Ishizaka\(^{(92)}\) obtained from optimally interpolated circulation fields. Ishizaka’s assimilation procedure is that of direct insertion, where the phytoplankton values in the model were simply replaced by those estimated from the CZCS ocean color data. Three types of adjustment were applied to the other compartments (nutrient, zooplankton, detritus) to allow for conservation of biomass, and this seemed to make little difference to the results obtained. The model was run forward from the assimilation time and the results compared with CZCS data at later times (comparisons made over a period of a few days). Two cases were considered, one in which the biological interaction and upwelling/downwelling terms were switched off, so that the resulting biological distributions were due purely to the physical advective and diffusive processes, and one where the biological interactions were included. The results suggested that advection dominated in this case, with biological processes acting as a secondary factor. However, the impact of the data assimilation lasted only a few days, indicating the need to assimilate data frequently (every 1–2 days) to keep the model updated and the errors in prediction small. Assimilation of the data had a positive effect overall, but did degrade some aspects of the model (estimates of nutrient fluxes as compared with in situ data). Ishizaka\(^{(90)}\) also tested the impact of only assimilating data over part of the region modeled, thus simulating the effect of partially cloudy data. This too seemed to give improved results, though it did cause discontinuities at the boundaries between the areas where data were available for assimilation and where there were none. Direct insertion of data is known to cause problems in the physical model, as the model adjusts by radiation of waves,\(^{(96)}\) but this did not appear to cause problems for the advective–diffusive biological model used by Ishizaka.\(^{(90)}\) One observation to be made about the study is that the use of a vertically integrated model avoids the issue of how to relate the satellite surface observation of chlorophyll to the subsurface structure in the biology (there being none in this model, as there is no depth dependence). Subsequently, Ishizaka\(^{(93)}\) has reported some preliminary results on the use of direct insertion with simpler ecosystem models. He concludes that, “... assimilation of phytoplankton data into a simple time-dependent model is not straightforward. Differences in error sources, methods of assimilation, and the timing of the assimilation all result in different model solutions. ... Furthermore, much more complex ecosystem structure is preferable for the real simulation and this increases uncertainty of the effects of the data assimilation.”\(^{\text{}}\)

Sarmiento et al.\(^{(57)}\) compared their results for the seasonal chlorophyll distribution of the Atlantic Ocean, obtained by embedding the Fasham et al.\(^{(84)}\) ecosystem model in a ocean general circulation model, with data from CZCS (of the type shown in Figure 1). They found reasonable agreement overall, but some specific discrepancies. Armstrong et al.\(^{(94)}\) followed this up by attempting to assimilate CZCS data into the same model at frequencies of 1 and 5 day\(^{-1}\). Comparisons improved overall compared with the unforced case of Sarmiento et al.,\(^{(57)}\) except at high latitudes, with the more frequent forcing giving better results. Sarmiento et al.\(^{(51)}\) attributed the discrepancy at high latitudes as being related to the modeling of the zooplankton grazing of the phytoplankton (see their paper for details). They therefore incorporated multiple grazing chains in the model, giving it a total of 13 compartments (nitrate, ammonium, bacteria and dissolved organic nitrogen, plus three compartments each for detritus, phytoplankton, and zooplankton).\(^{(94)}\) Assimilation of CZCS data at the same frequencies as before led to much better agreement. The assimilation technique used was “nudging”,\(^{(86)}\) applied to bring the model chlorophyll values in the upper layer of the model (top 10 m) towards the surface observations from CZCS. This procedure requires the model to adjust the subsurface biological distributions and violates the conservation of biomass, which is either added or removed from the model depending on whether the satellite–model difference in chlorophyll is positive or negative. Simplistically one might think that forcing the model values towards the observations would eventually result in complete agreement, but this is not the case owing to deficiencies in the model physics and biology. This is a case of using data assimilation to fit a model to data and thus to improve the model.

The previous two models discussed were two-dimensional (horizontal) and three-dimensional in space. A one-dimensional (vertical) model has been developed by Prunet et al.\(^{(95)}\) This is a 10-compartment ecosystem model coupled to a one-dimensional mixed layer\(^{(95)}\) and the data assimilated are from Station Papa (Station P; 50°N, 145°W). The difference from the other studies is that Prunet et al.\(^{(90)}\) assimilated data into both the biological and the physical components of their model. A variational assimilation technique was used. In their first paper\(^{(95)}\) they considered assimilating only surface chlorophyll data into the model and found that this can only partially constrain the parameters of the model and does not constrain the vertical structure of the chlorophyll. In their second paper\(^{(96)}\) they used a simpler four-compartment ecosystem model (nitrate, phytoplankton, zooplankton, detritus) coupled to the same mixed layer model as in their first paper.\(^{(95)}\) They found that surface chlorophyll assimilation is not sufficient to reproduce the seasonal cycle of surface chlorophyll, temperature, and nitrate in a robust manner. By additionally assimilating surface nitrate and temperature the model is
improved. Comparison between the two models suggests that choice of model structure can affect the results obtained. Although satellite ocean color data have not been used in these studies, they are important as they show that satellite-derived surface chlorophyll values on their own may not provide sufficient information to constrain models through data assimilation. Despite this, it is undoubtedly the case that as new ocean color data become available from the next generation of sensors, they will be used in assimilation studies (along with other data) to improve the biophysical modeling of the oceans.

4.5 Dimethyl Sulfide, Climate, and Gaia

It is known that various species of phytoplankton produce dimethyl sulfoniopropionate (DMSP), a precursor of DMS.\(^1\)\(^,\)\(^97\) Some time ago Charlson et al.\(^98\) proposed a link between the DMS originating in the ocean due to phytoplankton and the formation of cloud condensation nuclei (CCN) in the atmosphere. The DMS is oxidized in the atmosphere to form sulfate particles which act as CCN. Changing the CCN concentration affects the formation of clouds, which in turn influences cloud albedo and hence the climate. Changes in the climate in turn affect the phytoplankton in the ocean, thus providing a feedback mechanism. Under the Gaia hypothesis of the Earth as a self-regulating system,\(^97\)\(^,\)\(^99\) the increased albedo of the earth would reduce the temperature and light beneath the clouds, and so reduce photosynthesis and the growth of DMS-producing phytoplankton. Less DMS would in turn mean fewer CCN, fewer clouds, and an increase in light allowing more phytoplankton to grow. These feedbacks would allow the climate system to remain in balance.

In order to understand this process better, attempts have been made to estimate the flux of DMS from the ocean to the atmosphere. One of these has made use of CZCS ocean color data.\(^1\)\(^,\)\(^100\) Using an empirical relationship between the CZCS chlorophyll data and DMS, together with a gas transfer coefficient estimated using climatological winds (see section 4.2.1), Thompson et al.\(^100\) are able to estimate the flux of DMS from atmosphere to ocean. They note that the complexity of the phytoplankton production of DMS means that a valid relationship between the two will only exist in certain regions and at certain seasons. This is due to the fact that the production of the DMS precursor DMSP is highly species-specific.\(^1\)\(^,\)\(^101\) There are also considerable (factor 2) uncertainties associated with the DMS gas transfer coefficient.\(^1\)\(^,\)\(^101\) Nevertheless Thompson et al.\(^100\) were able to obtain estimates that are consistent, for a specific region and season, with in situ measurements and an estimate based on photochemical model and atmospheric measurements. They note that future ocean color sensors with increased spectral resolution may enable a more robust determination of the relationship between phytoplankton and DMS to be established, by providing quantitative information on species abundance or on the productivity of those phytoplankton groups that are strong producers of DMS. It should be noted that anthropogenic emissions of sulfur far exceed those from phytoplankton. Therefore, their impact on the climate system, particularly in the industrialized northern hemisphere, is greater.\(^1\)\(^,\)\(^5\)

4.6 Commercial Application – Fisheries

Although the primary focus of this article has been on the use of remotely sensed ocean color data for research into biological oceanography, it is worthwhile mentioning briefly that the data have also been successfully used for commercial purposes. The importance of commercial applications of the data is evidenced by the fact that SeaWiFS was launched and is operated by a commercial company OSC. The primary commercial application of ocean color data is in fisheries.\(^102\) It has been used, often in conjunction with SST data, to guide fishermen and fishing vessels to areas where fish might be found. This use is based on the food chain principle that an abundance of phytoplankton leads to an abundance of zooplankton that feed on them. This in turn leads to an abundance of fish that eat the zooplankton. Thus the presence of high levels of phytoplankton, as measured by changes in ocean color, is taken to indicate the potential presence of fish. More sophisticated approaches that take into account the preferences of certain fish species for particular temperature conditions (hence the use of SST in conjunction with ocean color), can be used to determine where to fish.\(^103\) Even in a situation where fish catches are limited by legislation (as is the case for European Community countries), the time and fuel saved in searching for fish may improve the profitability of fishing, a tangible benefit to the fisherman or fishing fleet operator. SeaWiFS data are being used to provide such services for fishermen, as CZCS data were in the past.

4.7 Possible Future Applications

In this final section a number of possible future applications of ocean color measurements from space will be briefly discussed. These are not exhaustive, but are given here to show the potential for the use of ocean color data. Despite the many existing applications that have been discussed above, which were based primarily on the use of CZCS data, the data from the new improved ocean color sensors (OCTS, SeaWiFS, MODIS, MERIS) will doubtless lead to the development of many new applications.
4.7.1 Discrimination of Different Phytoplankton Species

As discussed in section 4.1.3 it has already proved possible to gain information from ocean color measurements on one particular species of phytoplankton, namely coccolithophores. One paper\(^{(104)}\) has shown that it may be possible to detect blooms of the cyanobacterium *Trichodesmium* (a species of phytoplankton), using CZCS data. With the increased spectral discrimination and more bands that will be available from future sensors (MODIS, MERIS) it may be possible to discriminate between different species on the basis of their photosynthetic pigments. Different combinations and amounts of pigments in different species will produce varying responses in the light spectrum, as measured by the color sensors. The standard algorithms being proposed for MODIS include one for the detection of coccolithophores.\(^{(9)}\) No doubt other algorithms will be developed as the data become available, as was the case for CZCS.

4.7.2 Measurement of Other Biochemical Constituents

In the earlier discussion of applications (sections 4.1, 4.2, and 4.5) it was shown that even the rather limited CZCS data were able to provide some information on a variety of biochemical constituents apart from chlorophyll-a. The new generation of sensors should allow further studies of DMS, carbonyl sulfide, \(p\text{CO}_2\), and other chemical constituents related to the phytoplankton. MODIS algorithms have been developed to retrieve information on the algal pigment phycoerythrin.\(^{(9)}\) In addition, MODIS and MERIS are capable of measuring the phytoplankton fluorescence peak at around 685 nm (see Tables 6 and 8, and Esaias et al.\(^{(9)}\)). Of the light energy absorbed by phytoplankton chlorophyll, a small amount O(1%) is re-emitted as fluorescence.\(^{(11)}\) This provides an alternative means of measuring chlorophyll-a, as demonstrated by Neville and Gower\(^{(105)}\) using airborne measurements. Again as data become available, more new algorithms will be developed.

4.7.3 Use of Data with Models and in situ Measurements

One area that has been hampered by the lack of ocean color data is that of the use of models and in situ measurements. This is a developing area of study, both in terms of the use of data for model validation, and for the improvement of models by data assimilation (see section 4.4). Computer power has increased in such a way that high-resolution coupled biophysical models of entire ocean basins are now possible. Ocean color data can contribute to the validation of such models,\(^{(57)}\) to the study of specific processes,\(^{(56,106)}\) and to the improvement of the models through data assimilation.\(^{(84)}\) Interestingly all these examples are of the North Atlantic Ocean, one of the most studied ocean basins. The improved quality of the data from the new generation of sensors will add impetus to such studies. However, there will be a continuing need to make in situ observations to complement those from ocean color sensors, in order to understand and model other components of the ecosystem and their changes with depth.

4.7.4 Monitoring of Harmful Algal Blooms

The environmental and economic impact of harmful algal blooms (HABs) have increased as human activities influence the coastal ecosystem. Various types of phytoplankton produce toxins that can poison fish, thus affecting fisheries and commercial fish farming, or through shellfish that can enter the food chain and cause the poisoning of human beings (for a recent review see Richardson\(^{(107)}\)). The early detection of such blooms could help in preventing or alleviating some of the consequences that follow. In some literature HABs are referred to as “red tides” indicating that the presence of these harmful phytoplankton changes the water color to red or brown. The resulting color change can in principle be detected using ocean color measurements, though it may not be possible to distinguish changes in color due to harmful and nonharmful phytoplankton.\(^{(108)}\) The new generation of ocean color sensors provides the opportunity to detect HABs from space and to monitor their development and impact.

4.8 Afterword

The preceding review of the use of remotely sensed ocean color data to study biological oceanography makes no claims to be comprehensive or exhaustive (at least a book would be required to do the job properly). Instead the aim has been to give an overview of what has been achieved using the somewhat limited CZCS data set that has been available. The potential of data that are becoming, or will become, available from the new generation of satellite ocean color sensors (OCTS, SeaWiFS, MODIS, MERIS) has also been indicated. The availability of these data mean that an exciting period in the development of satellite-based biological oceanography is just beginning.

REFERENCES

Topographic modeling consists of producing a digital description of the relief of a given area. This description is generally given on a regular grid in two coordinates. The product consists of the value of the altitude of the terrain for each position of the grid, with respect to a reference shape such as an ellipsoid (approximation of the shape of the Earth) or the geoid (shape of the potential of gravity at sea level). The grid itself is defined in a cartographic or a geographic coordinate system. Common systems include the Universal Transverse Mercator (UTM), Lambert or, alternatively, coordinates in latitude/longitude. Topographic data are used in a variety of applications, from the correction of geometric distortion in remote sensing images to the prediction of the volume of materials to be removed in public works. Their applications include military uses, such as collision avoidance for low-flying aircraft or missiles, or civilian ones, such as optimal positioning of transmitters to cover an area for mobile communications. Radar interferometry is a promising technique for producing topographic maps on a large scale. It makes use of the very peculiar features of the images produced by synthetic aperture radar (SAR) instruments placed on board satellites. Used in differential mode, this technique can also produce a unique product: the map of the displacements which occur in a given area between two passes by a radar satellite. Again, the data can be organized as a digital file placed on a grid similar to the ones used for topographic mapping. However, in the case of displacement measurement, the useful piece of data placed on each node is the displacement experienced by the node, expressed in appropriate units of length. As for each new technique, there are a number of points to take care of before interpreting the data. The purpose of this article is to describe the radar data, both historically and technically, and to detail their two main applications in topography and displacement mapping. The main issues of the interpretation and the availability of the data are covered. Finally, we compare the performance of radar interferometry with other techniques, in both domains, and we try to outline its future.

1 INTRODUCTION

Radar imagery is often thought of as a substitute for the optical image, when the latter is not available because of cloud cover. This way of seeing things is doubly false.
because on the one hand, radar imagery has unique applications, which cannot be matched by optical imagery, and on the other hand because radar imagery is not completely insensitive to cloud cover, which is one of its main limits in the applications that we will discuss in this article.

After a brief history of radar imagery which will be followed by a description of the main technical characteristics of radar images, we will discuss one of the most spectacular techniques made possible with this type of data: interferometry.

This technique mainly produces two kinds of information, usually mixed together on the same image: topographic information and information on ground shifts. There are also undesirable contributions due to changes in the atmosphere during imaging. In order to avoid interpretation errors, one must know how to detect these contributions.

We will discuss the principles of the interferometric comparison of radar images, the limits of this technique and the systematic contributions that must be removed. Then we will go into the details of topographic computation using interferometry, which can produce, in the best case use of satellite data, altimetric accuracy of 1 or 2 m on cells with 30 m sides. We will then discuss the details of the computation of shifts on the Earth's surface, for which accuracy of the order of 2 mm has already been observed.

We will also address the problem of ambiguous interpretation and how to deal with it, the availability of space- or airborne systems, archives of radar data and software processing tools. Finally we will compare interferometry with competing techniques, by pointing out its advantages and disadvantages, and finish with the prospects for space missions dedicated to this technique.

2 HISTORY

Radar imagery is almost as old as radar itself. Radar instruments were flown on aircraft at the beginning of the 1940s, with detection goals similar to those of radar devices on the ground. The first processing intended to improve radar capabilities in terms of ground imagery date from the beginning of the 1950s, with "beam sharpening" techniques. The ultimate evolution of this processing, which allowed radar images to compete with optical images in terms of resolution, was formalized in the beginning of the 1960s. Wiley played a crucial role in these changes. Nevertheless, the computation requirements for the proposed processing led their designers to use analog methods based on optical computing with laser. The use of the phase of the radar signal by comparing two images taken simultaneously dates from the beginning of the 1970s. This was extended to two images taken at different moments from space at the beginning of the 1980s. In the mid-1980s, a suggestion was made that interferometry could be used to measure ground shifts. Because so little new space data was available, it took several years before the technique, with various capacities, was demonstrated.

The first steps of radar processing have only historic value. Current data can be processed by everyday workstations without compromising quality, in a very reasonable time that can only decrease with the regular increase in computing power. The reproducibility of digital processing makes it easy to use computed interference.

3 RADAR IMAGERY AND THE PRINCIPLES OF INTERFEROMETRY

3.1 Physical and Geometrical Properties of Radar Images

The main difficulty with radar imagery is the large wavelength used. Some radio waves have the advantage of passing through clouds, but their wavelength is larger than optical ones by a factor of one hundred thousand. To obtain the same resolution as with an optical system, a radar system must therefore have an instrument aperture one hundred thousand times larger. To imitate an optical observation satellite such as Système Probataire Pour l'Observation de la Terre (SPOT), whose telescope has a diameter of more than 30 cm, a radar antenna of thirty kilometers would therefore be needed. It is then obvious that radar imagery cannot rely on the separating power of the instrument. Two ideas are used to replace it: firstly, range imagery, which allows different points on the ground to be separated by the time that the radar wave takes to complete the round-trip distance. This wave is sampled at tens of megahertz, which corresponds to separations of the order of tens of meters on the ground. Each sample includes the wave amplitude and phase. Secondly, there is Doppler imagery, which separates the points along the direction of the velocity of the radar carrier by detailed analysis of the phases of the successive radar signals. In order for these techniques to work together to obtain a well-resolved image in the two main directions, the instrument must look to the side (Figure 1). These principles and their consequences are discussed in detail in several papers. They allow the data provided by the instrument ("raw" data) to be converted into image data ("synthesized" data). We will simply mention the main characteristics here. The
ELEVATION MODELING AND DISPLACEMENT MAPPING USING RADAR INTERFEROMETRY

Figure 1 Viewing geometry of radar. The instrument looks to the side to take advantage of the possibility of sorting echo samples by distance (closed lines). Synthetic aperture processing permits points to be distinguished by their Doppler effect (open lines). Both principles work together to cut the antenna print into high resolution pixels.

Figure 2 Difficulties caused by the principle of distance imagery. Distance ordering is compatible with cartographic coordinates between points A and B. Between points B and C the slope of the mountain is mixed with the contributions of points in the valley which share the same distance, a phenomenon called layover. In particular, the top of the mountain is seen, in the distance, before C, even if C is found before the top on a map. A more conventional effect is found between the distances of C and D, where shadowing prevents any signal from returning to the radar. Unlike layover, shadowing may occur in optical images.

principle of range imaging creates specific artifacts, which have no equivalent in optics. Depending on the incidence angle of the radar wave, two points (for example the peak of a mountain and the bottom of a valley) can be at the same range from the radar and their contributions will be irretrievably mixed together in the same point of the radar image. This is the “overlay” phenomenon (Figure 2).

The principle of Doppler imagery, also called synthetic aperture, requires large quantities of calculations, a feature which is fortunately attenuated by current computer systems. It leads to a geometry of the image tied to the position of the radar carrier and to its velocity vector. The geometry of the image thus does not depend on the orientation of the radar, which makes locating it much more precise than for the equivalent optical imagery. On the other hand, the radar image has an unusual appearance because it functions in amplitude and phase. In short, a radar image is formed from complex numbers. An element of the final image (pixel) is thus the sum of complex numbers which are representative of the different elementary targets to be found in the pixel. The amplitude of two identical targets present in the same pixel may thus be reinforced if their phases are identical, or cancel each other out if the phases are opposite. In the general case, the amplitude of the “synthesized” radar image is characterized by scintillation noise (“speckle”), which makes reading it more difficult than for an optical image.

The phase information at the pixel level is the ultimate information on range, as the fractional part of the radar range when the latter is expressed in units of the wavelength. The phase of each pixel in the image, however, results from the interaction of multiple elementary targets located at various ranges within the pixel, and varies randomly between neighboring pixels in a same image. But if the configuration of the elementary targets does not change, the “random” contribution in the phase between two radar images can be eliminated by subtracting their phases point by point. The difference of phase will just reveal the change of range for the pixel globally. This is the principle of radar interferometry.

3.2 Interference between Radar Images

The phase of a radar image used in comparison with that of a second radar image, records all the differences in radar range between the two images. The two images that we merge to form the image of the point-by-point difference of their phases, called the interferogram, have, in general, different perspectives, since they were not acquired from exactly the same spot, and a time difference, since they were not acquired at the same moment. These two differences almost always occur together in an interferogram. The difference in time is eliminated in systems with two radar antennas that can create two images simultaneously. The difference in
perspective can disappear exceptionally, when a satellite passes over almost exactly the same point to acquire the second image.

These two differences are behind the two types of information provided by interferometry. The difference in perspective creates the topographic information in the interferogram. The difference in time creates information on displacement. Each of these differences is also responsible for difficulties when implementing the technique.

3.3 Limits Caused by Changes in the Geometry and the Surface

The difference in perspective between two images should be limited. Let us assume we have two distinct targets, located at two ends of a pixel (one close to the radar, the other far from it). The targets will always be mixed together on the same pixel. It can thus be understood that if the variations in phase undergone by the two targets during the change from one image to the other are approximately identical, the variation in phase will be significant at the scale of the pixel. In the opposite case, the phase difference between the two images will, again, result in random contributions, because they are variable within a pixel. The difference in phase cannot then be exploited.

In the limiting case where the targets are located, in range, at the two extremities of a pixel, the stability of the phase variation will be guaranteed by the stability of the incidence angle over the two images. If it changes, the pathlength between the two targets on one image will be different from the pathlength on the other image. For example, a pixel of 10 m observed with 30° incidence assumes a round-trip pathlength of 10 m between two extreme targets. In order to limit the variation of this pathlength to a fraction of the wavelength, for example 1 cm, the incidence angle in the second image must be between 29.967° and 30.033°! A more concrete way of showing this is to express the maximum acceptable difference in position between the points from which the images are acquired. For a satellite in orbit at an altitude of about 1000 km, this difference is of the order of a kilometer (Figure 3). One can therefore only combine images separated by a whole number of orbital cycles of the satellite, when it is supposed to be in exactly the same place, and actually is found within 1 km in general (section 7.1).

3.4 Elimination of Systematic Contributions

Even if the previous condition is fulfilled, the slight difference in the incidence angle between the two images will create a progressive shift from one image to the next. For example, even if this difference only creates a tenth of a phase cycle on a pixel, it will create a full cycle every ten pixels, and several hundreds of cycles over the width of an image. Interference fringes of this type, called “orbital fringes”, can be eliminated by computations based on the trajectories. Because of uncertainties in the orbit, some fringes may remain after this correction. These fringes are used to refine the trajectories in the same way that the alignment of mirrors is adjusted in an optical interferometer.

4 APPLICATION TO TOPOGRAPHIC CALCULATIONS

4.1 Set of Equations and Accuracy

The elimination of the orbital fringes leaves some “relief fringes”. By looking again at Figure 3, we can see that if the terrain changes elevation in a pixel, that is between the ranges $R_1$ and $R_2$, which do not change, the distance $R_4$ will be changed to $R_4'$. This alteration will be expressed by an additional pathlength revealing the relief. The pathlength will be observed as a phase difference between two adjacent pixels.
To avoid manipulating complicated geometric equations, it is practical to combine all the parameters involved in the altitude measurement, such as the orbital separation, the wavelength and the incidence angle, in one single significant value, the altitude of ambiguity. This is defined by the variation in altitude that produces a relief fringe. It does not generally vary much on one interferogram and is thus a simple and practical way to characterize one. Assuming a horizontal difference between image acquisition points of $d$, an incidence angle of $\theta$, an observation range of $R$ and a wavelength $\lambda$, the altitude of ambiguity $h$ is given approximately by Equation (1):

$$h = \frac{R\lambda \tan(\theta)}{2d}$$

(1)

Figure 4 shows an example of a topographic interferogram.

### 4.2 Suppression of the Measurement Ambiguity

In mountainous terrain, and after elimination of orbital fringes, an interferogram looks like a family of interference fringes analogous to contour lines, separated in elevation by the local value of the altitude of ambiguity (Figure 4). The main difference between this interferogram and a topographic map is that the “contour lines” present as fringes are not numbered. In fact, the radar signal does not allow an order to be attributed to the fringes since each one corresponds to geometric differences between images that are usually less than one hundredth the size of the pixel, which is beyond the possibilities of correlation measurements. The only method for renumbering the fringes, an operation commonly called “phase unwrapping”, is to analyze the continuity of the interferogram. This is what we do when we analyze a topographic map. The noisy areas on the interferogram, as well as the places where the topographic fringes are very close together, pose significant problems to algorithms for automatic unwrapping of fringes, for which many solutions have been proposed.\(^{7,8}\)

### 4.3 Dedicated Systems

Interferometry provoked a strong interest in the computation of topography. Given the sensitivity of interferograms to other factors, such as the variation in atmospheric thickness discussed in section 6.1, systems with simultaneous imaging, for which these contributions can be eliminated between two images, were preferred.

Even though space radar systems with two antennas can be imagined (section 8.3), this concept has mostly been used for airborne systems, which offer economic means of computing the topography with interesting operational characteristics. For aircraft, which are much closer to their target than a satellite, the distance between the antennas is at most several meters, and not a kilometer (section 3.3). It is therefore possible to install the two antennas on the same plane, with either a horizontal or a vertical separation. The distance between the two antennas is then well known. The main problem is to properly take into account the roll that affects the aircraft. This can make the observational base “wobble”.

### 5 APPLICATION TO THE MEASUREMENT OF DISPLACEMENTS

#### 5.1 Set of Equations and Accuracy

Assuming that orbital and topographic effects have been compensated for, an interferogram can reveal the variations in range linked to the time elapsed between images. Even though these variations may include atmospheric effects (section 6.1), they are mainly useful for measuring groundshifts. If one part of the landscape observed by an image has moved, this displacement will be seen as fringes on the interferogram. More precisely, if the displacement at point $A$ is represented

![Figure 4 Example of “topographic” interferogram on Mount Etna, Sicily. Each fringe corresponds to a change in elevation of 250 m.](image-url)
by a vector $D$ and the position of the satellite is $S$, in any common reference frame, this displacement will be expressed (Equation 2) by a number of fringes $n$ equal to:

$$n = \frac{2D \cdot (S - A)}{\lambda}$$

where the factor 2 takes into account the round-trip path and where $\cdot$ represents the dot product. The accuracy of this kind of measurement therefore depends on the direction of the shift and the way in which a fraction of a phase cycle can remain significant. Shifts directed towards the satellite are observed the best. On the other hand, for a shift along the ground track of the satellite, where $D$ is perpendicular to $(S - A)$, the interferogram is not modified. The vector $(S - A)$, after being normalized and expressed in a geographical reference frame (for example: North, East and Up), gives a precise view of the sensitivity of the measurement. For example, a typical value for a satellite such as the European radar satellite (ERS) launched in 1991, ERS-1, is, for mid-latitudes, $(-0.08, 0.35, 0.93)$. The significant fraction of the phase cycle depends on the signal-to-noise ratio on the interferogram, which is a result of the power of the radar signal but even more of the way in which the layout of the elementary targets has been maintained in the time elapsed between two images. From this point of view, a desert, rocky or urban landscape would be very favorable, an aquatic landscape (ocean, river or swamp) would not yield any result and a landscape covered with vegetation would give an average result depending on the elapsed time and the way in which the radar waves pass through the vegetation to reach “solid” targets on the ground. Long wavelengths manage this more easily. The signal-to-noise ratio of an interferogram is therefore essentially experimental data. Accuracy of the order of 2 mm have nevertheless been confirmed in favorable cases. Accuracy also depends on the way the other components of interferometric information have been removed. For example, if the interferogram used for measuring shifts has an altitude of ambiguity of 100 m, and the terrain model used to remove the topographic contribution may have errors of 20 m, one-fifth of a fringe of topographic origin may remain. If the wavelength is 5 cm, a “noise” corresponding to 0.5 cm (1 cm for the round-trip path) will remain in the interferogram.

5.2 Examples of Use

Measuring shifts with interferometry is more interesting than topographic measurement, because there is almost no competition (section 8). The limitations of the technique are threefold:

1. the ambiguous character of the measurement, which must be unwrapped;
2. geometric sensitivity which varies depending on the direction of the displacement;
3. applicability which depends on the type of terrain observed.

They have not prevented spectacular developments in the measurement of deformations caused by earthquakes, glaciers, volcanoes and even phenomena with smaller amplitudes like post-seismic motion or continental drift. In the field of hydrology (Figure 5), interferometry has proved to be capable of measuring the quantity of water pumped by a geothermal plant. Irrigation also has a direct effect on the phase, which may come from geometric causes (swelling) or physical ones (change in electrical conductivity).

![Figure 5 Example of a differential interferogram. In California, the East Mesa Geothermal plant created a subsidence bowl by pumping water for two years. Each fringe represents about 30 mm of deepening. The ellipse-shaped bowl is 18 km by 10 km. The volume of the bowl stands at 4 million cubic meters where the loss of water recorded by the plant over the same period stands at 5 million cubic meters. Blurred areas to the west are used for agriculture, so that the soil did not keep the stability required for interferometry over the 2 years which elapsed between image acquisitions.](image-url)
6 AMBIGUITY OF INTERPRETATION

6.1 Signature from Various Contributions

A system for classifying phase structures should be used to enable correct interpretation, if several interferograms are available. The following in particular can be distinguished:

- Structures tied to the orbital difference: this involves phase structures viewed in several interferometric combinations of images, with an amplitude proportional to the topographic sensitivity of the interferometric pairs, which itself is tied to the distance between their orbits. This behavior characterizes the non-compensated or poorly corrected topographic residual.

- Atmospheric artifacts: this term includes structures that appear, with the same amplitude, in all the interferometric combinations of a given image. This behavior characterizes heterogeneity in the conditions of atmospheric propagation at the exact moment of image acquisition. Because the responsible image can be identified, the sign of the artefact is known. Artifacts that lengthen the trajectory are attributed to pressure waves or to turbulence in the troposphere and those that shorten it to local neutralizations in the ionosphere.

- Structures that depend on a date: this involves phase structures viewed with the same amplitude in several interferometric combinations of images, whenever the acquisition dates of the images that form them include a particular date. This behavior characterizes geophysical events like earthquakes.

This list can be expanded, for example with phase structures viewed in interferograms with an amplitude proportional to the time elapsed between the two images that form them. This behavior characterizes geophysical deformations that are continuous in time.

6.2 Methods for Improving Interpretation

Various simple methods can improve the appearance or content of interferograms. Numerous filters have been proposed. The simplest one recombines the phases of an interferogram with the corresponding amplitude from the source radar images, then averages the complex numbers formed this way in a neighborhood. The phase of the averaged complex number formed this way will be much less noisy than the initial phases, with some deterioration in the spatial resolution of the image. This method assumes that the interferogram has already had its densest fringes removed, in particular the orbital fringes, otherwise an average might blur the results.

One can also use the systematic characterization of the contents of the interferograms described in section 6.1 to attenuate or amplify this or that contribution. For example, if an interferogram has, because of the orbital gap of the images that form it, a topographic sensitivity of one fringe for 100 m of difference in elevation, while another interferogram has only fifty meters, the combination of twice the first interferogram minus the second will not contain any topographic effects. If the combination of different interferograms can be done with whole multiplying coefficients, the combination is possible before any fringe unwrapping.

7 AVAILABILITY OF DATA AND SYSTEMS

7.1 Availability of Archived Radar Data

Space radar images that can be combined must come from the same satellite, or from two identical satellites that are in almost the same position (typically within a kilometer, section 3.3) at different times. Satellites repeat their position at the end of their orbital cycle. Among the usable satellites is ERS-1, which went through two distinct 3-day orbital cycles, now completed, and a 35-day cycle which it is still in and which has taken up the largest part of its mission. The ERS-2, satellite, launched in 1995, has a radar identical to that of ERS-1, and is therefore compatible. It is on the same 35-day cycle, but with a one day lag ("tandem" concept). By combining the ERS-1 and ERS-2 data, one can thus obtain gaps of 35, 34 or 1 day. The data are in C-band (wavelength 5.6 cm). Still in C-band, but incompatible with ERS because of orbital and instrumental differences, are the data from RADARSAT (Radar Satellite of the Canadian Space Agency), a Canadian satellite launched in 1995, with a 24-day cycle and which features the possibility of imaging with various incidence angles. In L-band (wavelength 23 cm), there are data from the Japanese Earth Resource Satellite (J-ERS), which is on an orbit with a 44-day repeat cycle. Intrinsically less accurate than C-band, L-band can obtain better results on terrain covered with vegetation, since the longer wavelength can penetrate the vegetation and reach the ground. Short experiments have also taken place with radar on board the space shuttle (Shuttle imaging radar (Sir), Sir-A, Sir-B and Sir-C missions).

7.2 Availability of Processing Tools

The usefulness of radar images for computing topography and groundshifts involves a much larger public than the community of specialists working with this type of image. It is therefore necessary that the various processing steps be conducted by non-specialist users.
The processing steps include

1. the synthesis of radar images from raw radar data (section 3.1). Images that are already synthesized are available on the market;
2. the point-by-point registration of the two images to be combined by resampling;
3. the computation of the phase difference;
4. finishing work which includes fine-orbit adjustment and aligning the product in the desired cartographic geometry.

This processing is accessible to non-specialists who use scientific or off-the-shelf software. Commercial software uses standard workstations. When processing radar data one should begin with raw data. The inconvenience of this is the large quantity of computations to be performed, but though these computations are long, they are controlled by simple parameters and do not present any problem. On the other hand, the raw data are easier to concatenate than the processed data (when one site extends over more than one image in length). Optimal implementation of interferometry requires that the processing parameters for scenes to be combined be identical rather than optimized for each scene, which would be the case for scenes processed in a conventional fashion. The use of raw data with interferometric goals can impose a common value on these processing parameters, a compromise between recommended values for each scene. Finally, ordering scenes in raw form may be less expensive.

7.3 Principle of Data Selection

The choice of radar images to be combined with interferometry depends on the aim of the measurement and the nature of the terrain to be observed. For topographic computation, short time differences are preferable (the ideal being simultaneous images) as are altitudes of ambiguity compatible with the type of relief observed. For example, if altitude differences of 1 km are in the scene, it is preferable to choose an altitude of ambiguity of 100 m rather than an altitude of ambiguity of 10 m, although it may mean restarting with a lower altitude of ambiguity after a first pair has roughly calculated the topography. Finally, it is always necessary to check the elevation map with several sets of data, in order to tag atmospheric artifacts. For measurements of drifts that are constant in time, one should wait until the drift reaches a measurable amplitude. For instantaneous motion (earthquake), the images must simply be taken before and after the event. For measuring motions, data with a high altitude of ambiguity are favored, to make it easier to eliminate topographic contributions. In all cases, climatic considerations are involved. In Iceland, one can only work with images acquired in summer because of the snow. Paradoxically, it is sometimes better to work with images taken at an interval of one year rather than six months, because of seasonal cycles. One can take advantage of the capability of radar to work at night. Since it is an active instrument, it is its own source of light and at night the atmospheric conditions and states of vegetation are more stable. When there is dense vegetation, it is better to use L-band data. The choice of optimal data is thus largely a question of opportunity and depends on the know-how of the specialist of the object of the measurement and on his knowledge of the sites.

8 COMPARISON WITH OTHER METHODS AND PROSPECTS

8.1 Comparison with Stereoscopy for Topographic Measurement

In optical stereoscopy, the difference in perspective between the images creates a deformation that depends on the relief, and this deformation is used to compute the relief. The critical parameters of the method are the pixel size and the “base-to-height” ratio. The smaller the pixel the better the measurement of the deformation. Depending on the measurement methods used, it is possible to detect deformations with an accuracy equal to a more or less large fraction of the pixel size. The “base-to-height” ratio affects the extent of the deformation, for a given relief. In optical stereoscopy, one can obtain a ratio of one. That is to say, that the distance between the points from which the images are taken is equal to the altitude of the imaging instrument. In these conditions, an elevation difference in the observed landscape is expressed by a deformation of the same size between the images. The accuracy in altitude is then equal to a fraction of the pixel size, or typically a few meters.

In radar interferometry, the base-to-height ratio is obviously very low, as we saw in section 3.3, and can hardly exceed one thousandth. Even though the equations of geometric sensitivity to the difference in altitude are different from those in optics, one can conclude that over a given relief the deformation between two radar images which can be combined by interferometry is typically one thousand times less than that of two stereoscopic images. On the other hand, the measurement is based on the phase difference, which allows, depending on the wavelength and the power of the signal, an accuracy of the order of a centimeter to be obtained. This accuracy compensates for the small base and helps explain why the results of the two methods are quantitatively comparable. They both lead to accuracy of a few meters
for elevation measurements. They are, however, very different qualitatively.

Interferometry can function all-weather and thus offers the total certainty of a result. It is nevertheless necessary to check this result with several trials in order to detect the contribution of atmospheric effects. Furthermore, some surfaces, like forests, only yield mediocre results. In comparison, stereoscopy with an optical satellite with lateral repositioning will have a low probability of success in case of dense cloud cover. For example, if a territory is free of clouds only 10% of the time, the probability of obtaining an image pair without clouds is only 1%. If the satellite can acquire the two images by looking ahead, then behind (along-track stereoscopy), the probability stays close to 10% but no space stereoscopic system of this type currently exists.

Interferometry is superior over flat and poorly contrasted terrain, for which the correlation between optical images “does not work”. It is also better in background quality. For weak altimetric signals, interferometry produces a rather smooth result while the correlation residuals are noisier. On the other hand, optical stereoscopy is better for terrain that is mountainous, contrasted by types of surface and differences in lighting. In these areas, the geometric problems of radar such as overlay and shortening have major impact. Besides, it is difficult to count the numerous fringes in these areas, and they may even be interrupted.

The structure of the error generated by each technique is very different: the atmosphere is “all or nothing” in optics. If there are clouds, no measurement is possible. In radar interferometry, the atmosphere introduces an undetectable measurement bias, except by comparing several results over the same site. The error in radar is thus more concealed.

8.2 Comparison with Global Positioning System for Measurement of Shifts

There are no existing techniques which compete with interferometry for measuring groundshifts from space. While it is possible to measure these shifts by comparing optical images taken before and after the events, one is unlikely to obtain measurements whose accuracy would be much better than a meter given current civil optical satellites. On the other hand, using specific devices on the ground, it is possible to obtain local measurements of very high accuracy, in particular with the differential global positioning system (GPS) technique.

The advantages of this technique are

1. its relative insensitivity to the nature of the ground over which the receiver is installed, provided that the ground is stable and the site is obstacle free;
2. its ability to measure in three dimensions, even though the measurement of the vertical component is less accurate than the others.

Depending on the conditions and the integration times, the measurement accuracy can be less than a centimeter. The advantages of interferometry are

1. lower cost (excluding from the computation the cost of the satellites in both cases, GPS and radar, since the missions of the space systems go beyond geodesy);
2. a measurement with very high spatial density, at least one point per hectare in general, which allows better understanding of phenomena with complex morphology.

8.3 Prospects for Dedicated Space Missions

Interferometry has produced very spectacular results\(^{17}\) by using data from radar satellites that were not designed for this goal. Nevertheless, the technique is so efficient that all future radar missions will take its particular requirements into account. In order to consider one or more space missions dedicated to interferometry, they must promise decisive advantages. We will distinguish between topographic applications and dynamic applications.

For topographic applications, the main difficulty comes from the atmospheric contribution. To suppress it, simultaneous image acquisition would be sufficient. This can be done either with a satellite with two antennas, or with a system of two very close satellites. In the first case, the system is very specific and its precision is limited by the difficulty in constructing a long beam to separate the two antennas sufficiently. This idea is, however, at the base of National Aeronautics and Space Administration (NASA)’s Shuttle Radar Topography Mission. In the second case, the system is less specific but there must be two copies of the satellite. To eliminate atmospheric effects, the two satellites must fly at an interval of a few seconds so that the atmosphere has not had time to change. The European Space Agency (ESA) experiment which consisted of flying the ERS-1 and ERS-2 satellites with a one-day interval did not succeed from this point of view. One can also imagine that one of the two satellites is passive and just receives the signal, which would lower the cost, but make the mission more specific.

For applications related to ground motions, the added value of a dedicated system mainly resides in its capacity to reuse old radar archives, in order to highlight slow shifts on image pairs taken at very different times. Other technical elements are important, but less specific: precision in the repeat cycle of the trajectory
which minimizes the topographic contribution, auxiliary instruments that provide simultaneous information on the state of the atmosphere, the capability of pointing with different angles and the capability for using varied wavelengths. Being able to reuse an archive will require a satellite with very precise technical characteristics, which must cover the same orbit as its predecessor, use the same wavelength and have the same orientation. Several mission concepts have been proposed. Their success will depend on their capability to distinguish themselves from conventional radar satellites of the future, which will all have interferometric capability.

Elevation Modeling from Satellite Data

Thierry Toutin
Canada Centre for Remote Sensing, 588 Booth Street, Ottawa, Canada, K1A 0Y7

1 Introduction

Most geoscientific applications using georeferenced cartographic data need a good knowledge and visualization of the topography of the earth's surface. For example, mapping of geomorphological features is hardly feasible from a single image; three-dimensional (3-D) information has to be generated or to be added for a better interpretation of the two-dimensional (2-D) data.

Since the early emergence of earth observation satellites, researchers have investigated different methods of extracting 3-D information using satellite data. Apart from a few early stereoimages acquired with hand-held cameras during the Gemini and Apollo missions, the first experiments to extract 3-D data using stereoviewing from space began with the Earth Terrain Camera (ETC) flown on board SkyLab in 1973–74.

Since these early experiments, various analog or digital sensors in the visible or in the microwave spectrum have been flown to provide researchers and geoscientists with spatial data for extracting and interpreting 3-D information on the earth's surface. Although the shape-from-shading technique can be applied to optical sensor (OPS) images, stereoviewing using space camera or digital scanner images was, and still is, the most common method used by the mapping, photogrammetry and remote sensing communities.

However, side-looking synthetic aperture radar (SAR) data also give the opportunity to extract 3-D information using image-processing techniques appropriate to the nature of the data. With SAR data, three main methods have been developed: radargrammetry, clinometry and interferometry. Radargrammetry (similar to the stereoviewing of optical data) uses two images acquired from different viewpoints to generate a stereopair and stereoviewing. Clinometry takes advantage of the SAR shading and shadowing in the image, and interferometry uses mainly the SAR signal data instead of the image. Other methods (polarimetry and altimetry) are also used for 3-D information extraction.

This article reviews the different methods and sensors used to extract absolute or relative elevation and assesses their performance using the results from various research and commercial organizations. It also discusses the respective advantages, difficulties and constraints of the sensors, the methods and the technologies used to take into account the strength of each. It further assesses how they perform as complementary sources and systems for extracting elevation data in an operational context.

1 INTRODUCTION

At one time, a hilltop provided the best vantage point from which to observe nature's workings, but now discoveries in optics, photography and flight allow us to see the earth as never before. Advanced methods in computing and signal-processing technologies have enabled us to increase our ability to visualize, perceive and extract information from the earth’s surface. Today earth observation satellites orbit our planet collecting data to produce images, which allow us to monitor, understand and plan the use of our world's resources.

Remote sensing has evolved into an important supplement to ground observations and aerial photographs.
in the study of terrain features, such as the ground elevation. With the advent of instruments that produce images from electromagnetic radiation beyond which the human eye and cameras are responsive, human “vision and perception” have been greatly extended.\textsuperscript{(1,2)}

Why is it important that the third dimension be conveyed? Because humans are naturally able to see in three dimensions. The “naturalness” of a 3-D representation of reality enhances our ability to interpret 2-D imagery. Cartographers, engineers, geologists, hydrologists and other geoscientists use different 3-D viewing methods to perceive the ground elevation in order to understand better the earth’s surface. For example, representation of the third dimension supplies important information about the relationship between land shape and structure, slopes and waterways, surface material and vegetative growth.

A digital elevation model (DEM), which is a digital representation of the earth’s relief, is now one of the most important data structures used for geospatial analysis. Unfortunately, DEMs of usable details are still not available for much of the Earth, and when they are available they frequently lack sufficient accuracy. The digital format of a DEM made it easier to derive additional information for various applications, so that elevation modeling has become an important part of the international research and development (R&D) programs related to geospatial data.

Owing to the high spatial resolution of recent satellite sensors (Landsat–Thematic Mapper (TM), Système pour l’Observation de la Terre (SPOT)–High Resolution in the Visible (HRV), Indian Remote Sensing Satellite (IRS)–Linear Imaging Self-scanned Sensor (LISS), European Remote Sensing Satellite (ERS)–SAR, RADAR-SAT–SAR, etc.), a large number of researchers around the world have investigated elevation modeling and the production of DEMs. There is plenty of literature describing the methods, algorithms and accuracy assessment of DEMs\textsuperscript{(2–6)} including review articles.\textsuperscript{(7–11)} They have addressed different, but generally not all, aspects of DEM generation from satellite data. A completely comprehensive and up-to-date review is not available.

Furthermore, recent research into modeling computer vision on human vision has led to the advent of new alternatives applied to satellite imagery. Current research in computer vision assumes that if a computer program can be made to “see” things as a human would, the algorithm must have some basis in human vision. Consequently, to develop better an understanding of the different methods used to derive elevation from satellite images, the relationship between depth vision and perception and terrain elevation representation has first to be addressed. Only the basic concepts and the historical background of natural depth perception relevant for remote sensing applications are presented. The different methods (climometry, stereoscopy, interferometry, polarimetry and altimetry) are then presented and their applicability to the variety of data is reviewed (space photographs, digital sensor in the visible and infrared (VIR) spectrum and SAR). Finally, some concluding remarks on these methods and the future prospects of the next generation of satellites are presented.

## 2 HISTORICAL BACKGROUND AND BASIC CONCEPTS

### 2.1 Constructing the Third Dimension

Throughout history, humans have tried to represent what they saw and understood through images. Everything from cave walls, to canvasses, to computer screens have been used to express perception of our surroundings. Maps have provided one means of showing the relationship between humans and their environment. Towns, roads, rivers, mountains, valleys and where the land meets the sea have been drawn in an organized fashion for centuries. Mapmakers have always sought ways in which to represent both the location and the 3-D shape of land.

Mapmakers and other illustrators have traditionally used rendering techniques such as shading, overlapping and perspective views to create a 3-D effect. Leonardo da Vinci (1452–1519) demonstrated in 1492 the principles of optical projection. His German contemporary, Albrecht Dürer (1471–1528), produced an outline of the laws of perspective, and in 1525 he constructed samples of mechanical devices with which he made true perspective drawings of nature scenes. His devices included an apparatus for producing stereoscopic drawing.\textsuperscript{(5)} In the last 100 years, many advances in representing three dimensions have been made. Stereomodels, anaglyphs or polarized images, chromostereoscopic images and holograms can provide 3-D information about our planet whereas 2-D flat images cannot.

### 2.2 Vision and Perception

For humans, the information provided by the eyes undoubtedly plays the dominant role in our interpretation of the environment. However, the power to integrate the viewed image, to recognize its contour, its color and its relationship with other objects indicates that the process of vision does not merely consist of “seeing” but also of “perceiving” and understanding through the central nervous system. The eye, considered as part of the brain, is fundamentally an organizer. The eye/brain, starting with the activity of the retina, is actively building a world of objects: our mental model in psychology. This
ELEVATION MODELING FROM SATELLITE DATA

suggested that a priori knowledge is useful for a better interpretation and understanding of the image: to have a clear idea of what to look for, where to look and how to look.\(^1\)

Perception, or perceiving, refers to the process whereby sensory stimulation is translated into organized experience. That experience, or precept, is the joint product of the stimulation and the process itself. In the “depth” context, the visual system (the process) creates the 3-D world (the precept) we experience from the 2-D pattern projected on to the retinas (the stimulation). But the fact that we can see depth fairly well with one eye closed, or in a photograph or painting, indicates that two eyes are not necessary for a satisfying sense of depth. This dichotomy suggests an intimate relationship between what might be called “object recognition” and perception of three-dimensionality. Unfortunately, at this point, we know little about how the brain identifies objects, so a large portion of “depth perception” is not understood.\(^13\)

However, in modern psychology, it is accepted that depth perception is based upon four physiological cues (accommodation, convergence, binocular disparity and motion parallax) and six psychological cues (image size, linear perspective, areal perspective, overlapping, shade and shadow, texture gradient).\(^14\) These cues are treated as additional pieces of information which, when added to a flat picture on the back of the eye, make depth perception possible. The brain combines these cues in our mental model with the 2-D picture to produce judgements about the relationship of objects in space.

2.3 Depth Perception with Remote Sensing Data

Within the field of remote sensing, it is generally recognized that psychological factors, such as perception, play a major role, but researchers devote little time or no time to studying the psychological aspects of the remote sensing processes.\(^12\) In fact, it has been shown that the interpretation of cartographic information can be facilitated by using 3-D or perspective representations when compared with a flat 2-D display.\(^15\) Since terrain relief modeling is based on the principal concepts related to human depth perception, what are the main cues that play a role in depth perception of remotely sensed data? Perspective is the most popular and widely used with remote sensing data. It combines different cues such as linear perspective, overlapping and texture gradient. It also takes advantage of the viewer’s conceptual knowledge of the perspective phenomena. This psychological cue is thus only used for a representation and visualization of the terrain topography combined with remote sensing images and not for terrain modeling.

Shade and shadows are familiar phenomena, which can help one to judge the size and shape of objects by providing profile representations. It is particularly helpful if the objects are very small or lack tonal contrast with their surroundings. For example, large look angle SAR images, which approximate low sun angle aerial photography in order to accentuate minute surface irregularities, are becoming important in geological investigations.

Shading is sometimes confused with shadowing. Shading is the variation of brightness exhibited in the image. It arises primarily because some parts of a surface are oriented so as to reflect more of the incident illumination towards the sensor.\(^16\) Since shading provides cues all over the surface not just along special contours, this principle is used with the shape-from-shading technique to derive terrain slope and elevation. Shadow on a surface results when another surface intercepts the illumination from the source. It only provides localized cues (along special contours) to shape, although the shadow of a curved surface cast on another curved surface is very difficult to interpret. This principle is used to derive the elevation of specific targets such as buildings, trees, etc.

Binocular disparity and convergence are the two physiological cues when viewing imagery in stereoscopy. Binocular disparity predominates with optical images because it reproduces the natural process of human binocular vision. It is important when viewing radar images, but the shade and shadow cues also have a strong and cumulative effect on stereoradar imagery. As an example on a quasiflat terrain, the psychological cues overcome the binocular disparity when looking at the radar stereopair in pseudoscopy (apparent reversal of natural relief when inverting the viewing position of the two images).\(^17\) Owing to the specific geometric and radiometric aspects of SAR images, it may take our brain time to assimilate this non-natural stereoviewing, mainly when both geometric and radiometric disparities are large.\(^18\) However, since depth perception is an active process (brain and eye) and relies on an intimate relationship with object recognition, with experience radar images can be viewed in stereo as easily as VIR satellite images.\(^19\) This principle is used in satellite photogrammetry and radargrammetry by computing the terrain elevation from the measured parallaxes (related to the binocular disparity) between the two images.

3 SHADOW AND SHADE FOR CLINOMETRY

3.1 Basic Concepts

Shadow has been used for a long time in astronomy. In 1610, Galileo observed Moon spots. The first ambiguity was to determine if these spots were shadows or low
reflectivity surfaces. Looking at their evolution as a function of the sun illumination, he concluded them to be shadows from the moon relief.\textsuperscript{20} Later, the height of craters was determined using the lengths of shadows of the crater edges.\textsuperscript{20}

One of the first applications of shape-from-shading was used in robot vision to detect the 3-D shape of industrial objects with a diffuse reflecting surface. Using the principle that an image of a smooth object known to have a uniform surface will exhibit gradations of brightness, or shading, the shape can be determined to map the height of this surface. Because there are two degrees of freedom to surface orientation, the reflectivity does not uniquely determine the local normal but a set of possible normal directions. These directions describe a cone, whose axis is the illumination direction, and the half-angle the incidence angle. Consequently, local operation on the brightness alone cannot be used to determine the shape of the surface and its orientations. Additional constraint must therefore be added: generally the surface is assumed to be continuous and smooth, so that the surface orientations of neighboring surface elements are not independent. If the reflectivity function and the position of the illumination source are known, the shape can thus be obtained from the shading.

The application of this concept to remote sensing data is less evident owing to the sensitivity of shading to reflective properties of the earth’s surface. Even if this reflectivity function has been described with data from many experimental observations,\textsuperscript{21–23} a general Lambertian model is often chosen for simplification when a small range of incidence occurs.\textsuperscript{24} The local slope is then computed from the pixel reflectivity value and transformed into relative elevation by integration pixel by pixel. In other words, shape-from-shading makes uses of the sensitivity of microtopography, but it cannot provide absolute location. Some reference elevation information is needed to derive the absolute elevation. More details of VIR or SAR sensors are given in the following sections. In summary, the accuracy of this technique with remote sensing data is limited by intrinsic radiometric and geometric ambiguities:

1. The reflectivity is not only dependent on the local incidence angle, but also on the albedo related to land cover, rugosity, humidity, etc., as a function of the sensor. Miscalibration and SAR speckle are also sources of error.

2. The determined incidence angle yields a set of potential orientations whose normal directions describe a cone. Furthermore, this method only determines slopes, reference elevations have to be known and the accuracy is limited by the height error propagation.

On the other hand, cast shadow and occluded areas can also be used to extract relative heights\textsuperscript{25,26} or to determine ground control points (GCPs).\textsuperscript{27,28} The shadow areas occur when the ground surface is not illuminated by the source (“backslope” related to the illumination source), and the occluded areas occur when the ground surface is not visible from the sensor (“backslope” related to the sensor). Since the illumination source is the sensor with SAR images, the effects of these two concepts are mixed, but they are different with VIR images since the illumination source, the sun, and the sensor are different. While occluded areas are completely without information, shadow areas in VIR images have some information because the terrain receives some diffuse sun illumination partially reflected by the terrain. The impacts of shadow/occluded areas for VIR and SAR images are addressed in the next two sections.

3.2 Application with Visible and Infrared Images

For VIR images, shadow and occluded areas are different since the illumination source is the sun. Satellite VIR images are acquired from the descending path of a sun-synchronous orbit, and the local solar time is generally before or around noon (e.g. for SPOT, the local solar time of the descending node is around 10.30 a.m.). Consequently, west-looking images will have shadow and occluded areas in the same direction. Care must be taken to separate these two effects. Since the sun elevation angle around noon will generate shadow with steep slopes, it can be consistently measured only from vertical structures such as buildings or trees (in a row or isolated), or very rough terrain. However, with a low sun elevation angle (in wintertime), the relief perception of a rugged terrain is inverted.\textsuperscript{29} Occluded areas could only be used to extract elevation information with off-nadir viewing images, but this has been never addressed.

This method using shadow length measurements is largely used with aerial photographs in which the pixel resolution is much better than the object height.\textsuperscript{30} To our knowledge, no attempt has been realized with space photographs. Knowing the sun and sensor geometry, the same method can be applied to VIR images, such as panchromatic SPOT images, even if the resolution is coarser.\textsuperscript{24} Using a simple trigonometric solution, elevation was computed with 3.7-m accuracy over a sample of 42 well-defined buildings. A correction for the known terrain slopes was also introduced. Since the shadow length is manually measured at the pixel unit (10 m for panchromatic SPOT images), these good results can be accounted for by the size of the building (up to 60 m with a mean of 30 m), and the large shadow cast (up to 18 pixels with a mean of 8 pixels). Hartl and Cheng\textsuperscript{31} computerized the method and applied it over a complete
city. Only 30% of over 78,800 buildings were extracted, with calculated heights less than 20 m for 90% of them. Seventy-seven buildings were randomly selected to check their height error. The root mean square error (RMSE) was about 6 m, with only 11 buildings having errors larger than 10 m (SPOT resolution). The high building density and the overlapping of gray value were the main factors leading to the larger error.

Since shadow boundary is a key point in the process, different tools have been developed to determine it more accurately. Meng and Davenport\(^{32}\) created an edge-image template using the point-spread function of the sensor. After a manual rough location of the edge, a correlation process between the template and the actual image determines the best location of the shadow edge within 1/100th of a pixel. Unfortunately, no ground truth data have been provided for checking the accuracy.

On the other hand, Shettigara and Sumerling\(^{33}\) developed a four-step process using the spatial information of a panchromatic SPOT image and the spectral information of the infrared band of a SPOT image. First, an appropriate threshold to delimit shadows in the images is selected. Shadows cast by rows of trees are used to estimate the mean heights of trees. Calibration curves are then constructed to relate the actual mean heights of trees to the estimated heights. Finally, heights of industrial buildings are computed using their shadow lengths and the calibration curves, without any correction for the terrain slopes. A 3-m accuracy has been measured with only three 12-m tall buildings. Although the shadow determination is more sophisticated, the results are similar to those with the first method.\(^{26}\) The advantage of this method, when compared with the first one, is that the shadow boundaries are located with sub-pixel accuracy using an optimum threshold that enables smaller building heights to be estimated. The disadvantages are that two SPOT images are used, and some ground data for the tree-row heights are necessary to determine the calibration curves. Conversely, the first method does not use ground data for height estimation. No attempt to verify the method over a complete city in a real environment has been attempted, as with the first method.\(^{31}\)

Shape-from-shading can be applied to VIR imagery since information concerning the terrain is contained in multisensor data. With homogeneous surfaces where variations in reflectance may only refer to topographic surface differences, rather than to land cover effect, a simple reflectance model can be used to derive the topographic information. Lodwick and Paine\(^{34}\) used two Landsat-1 and -2 images (July and October) over an ice cap on Baffin Island, Canada, to obtain high and low sun angles and maximum difference in sun azimuth. They allowed for the reflectivity with a simplified Lambertian model\(^{21}\) and two empirical models to resolve the radiometric ambiguity. The slopes being in the sun-azimuth direction resolved the conic ambiguity. They first demonstrated with a training sample that the reflectance conditions of an ice cap are non-Lambertian for a large range of incidence angles, as did Smith et al.\(^{24}\) for pine-forest cover types. The first empirical model used a second-order polynomial computed over training samples. Difficulties in obtaining representative training samples were the main source of errors even if a high correlation was obtained. The second empirical model applied a simple linear model between typical maximum slopes in the “sun-facing and away-facing” directions and the reflectance values at the 1% level of the gray value histogram. It was the best solution to generate height differences, with broad agreement with values observed on the map.

Finally, a weighted third-order surface adjustment was carried out with nine control points to transform the 50-m posting slopes in the sun-azimuth direction into elevations. The results for the basic shape of the ice cap surface compared well with the base map. Some variations could be partly explained by the surges (melting and refreezing) of the ice-cap surface. No quantitative accuracy results were given owing to the lack of precise and digital topographic information.

These qualitative results should have generated some interest in the scientific community to expand on this work. However, no other results with different study site and data sets have been presented to date. It seems that most of the research effort on the applicability of the method has been directed towards SAR data.

### 3.3 Applications with Synthetic Aperture Radar Images

For SAR images, shadow and occluded areas are mixed, since the illumination source is the sensor itself. Therefore, they are completely without information and the boundaries of a cast shadow are easier to determine than with VIR images. Depending on the SAR look angles, only the steepest slopes produce shadow/occluded areas. Height determinations can then be made for the same type of vertical structures (buildings, rows of trees, etc.) for which such measurements have been made on VIR imagery. La Prade and Leonardo\(^{25}\) used simple trigonometric models and knowledge of the SAR geometry to translate measured shadows into heights. However, layover lengths have to be added to the shadow lengths to take into account the good positioning of the base of the vertical structure.

Cast shadows provide only localized cues to shape. On the other hand, shade provides cues all over the surface, not only along special contours. This radiometric information (the radar backscatter) of each image pixel is used in radar clinometry to determine the local
orientation of the terrain and then the elevation by the integration of slopes.

Radar clinometry, as an adaptation of photoclinometry developed by Horn, has been further developed by Wildey for the mathematical equations and later for its operational feasibility in anticipation of the Magellan mission to map Venus. Radar clinometry capabilities and limitations are well known, even if the research studies have been limited. At first, the principle appears simple: essentially the inversion of a mathematical expression of the radar backscatter in terms of the albedo and the local incidence angle. As mentioned previously, there are more severe limitations due to intrinsic radiometric and geometric ambiguities when the method is applied to SAR images of general terrain surfaces, and not only to homogeneous surfaces such as in the previous experiment with VIR images.

The first radiometric ambiguity is related to the inversion of the model since it depends on two parameters. The SAR backscatter of the surface is altered if the surface properties vary from place to place. In this case assuming uniform reflecting properties (constant albedo) will recover a shape (incidence angle) that is different from the actual one. This approximation, as an extension of photoclinometry, was also used with SAR by Wildey and Frankot and Chellapa. More sophisticated models, which take into account the SAR and surface interaction (surface geometry, vegetation, soil properties, geographic conditions, etc.) have been developed. They should now permit one to establish a more realistic backscattering model of the intensity than the traditional Lambertian model used for a homogeneous surface. No attempt to use them has been made due to a relative decline of the method in the scientific community during the last decade. Other radiometric problems that are not completely controlled and fully resolved are specific to SAR sensors, namely speckle, miscalibration and “discretized” sampling.

The conic ambiguity is related to the definition of the incidence angle. Even when accurately determined, it does not uniquely define the orientation of the surface but a set of possible orientations. Their normal directions describe a cone with the axis being the illumination direction. Since there are two degrees of freedom to surface orientation, it takes two numbers to specify the direction of a unit vector perpendicular to the surface. One brightness measurement at each picture cell only gives one equation for two unknowns at every cell. Additional constraint or assumption has to be made to resolve this conic ambiguity. One assumption implemented by Wildey is the hypothesis of local cylindricity. It enforces a local continuity between adjacent pixels to define a local cylinder. Since there is no iteration in the solution process, the local-cylindricity method is sensitive to integration approximations and image noise. It then tends to accumulate these effects along the full DEM reconstruction leading to “pseudo systematic” errors.

Other assumptions or constraints to resolve the conic ambiguity implemented by Frankot and Chellapa are the notions of integrability and regularization. The first states that heights can be integrated along any path since these values are independent of the integration path. This constraint acts as a smoothing process. The second limits the amount of allowable oscillation in the computed terrain surface. Furthermore, they used an iterative approach starting from an approximate existing DEM. Differences between gray values of the real image and the SAR synthetic image, predicted from the latest estimated DEM, are used to improve the terrain’s slopes and heights and to converge to the final DEM. In conjunction with the two previous integrability and regularization constraints, this approach tends to spread out the speckle noise errors instead of propagating them.

Thomas and Kober expanded this iterative approach to multiple images. Some spot heights derived from stereoscopy or other sources can also be added as supplementary constraints of the estimated heights. Using multiple image algorithms gives better stability and robustness with noisy images during the iteration procedure, as well as a faster convergence. However, it does not fully resolve the two basic ambiguities.

For the conic ambiguity, Guindon quantitatively demonstrated that the SAR image gray level is not an effective indicator of local incidence angle, and hence is not an accurate measure of the overall local terrain surface normal direction. It is only a strong indicator of the range component of the terrain slope. It can therefore only be used to derive elevation profiles for individual image range lines. Since no significant detectable information is available about azimuthal slope, an additional source of “azimuthal control” data is required to tie the adjacent range line elevation profiles to a common and absolute origin.

Paquerault and Maître therefore developed a two-step strategy to compute these two components of the incidence angle. First, they computed the range component from the backscatter gray-level pixel, and integrated it along a range line. They then applied a contextual Markovian strategy to modify successively, in a random order, each pixel orientation of the full image. This second step enabled them (i) to take into account the azimuth component of the incidence angle, (ii) to link together the adjacent range lines elevation profiles and (iii) to reduce the noise error propagation.

Despite the developments in the mid-1990s, SAR shape-from-shading remains a marginal technique, applied mainly in difficult situations such as tropical land cover or extraterrestrial sites without ground truth.
This is mainly due to the fact that the radiometric ambiguity between the terrain albedo, the radar backscattering cross-section and the incidence angle is rarely solved, except on a homogeneous terrain surface with a Lambertian model. However, a large part of the earth, without cartography, approximates to these homogeneous surfaces.

### 4 BINOCULAR DISPARITY FOR STEREOSCOPIC PAIRS

#### 4.1 Basic Concepts

In about 1600, the German astronomer Johannes Kepler (1571–1630), gave the first precise definition of stereoscopy, and a Florentine painter, Jacopo Chimenti, produced one of the first hand-drawn stereopicture pairs (Wicar Museum, Lille, France, ca. 1600).

In modern photogrammetry, “stereoscopy is the science and art that deals with the use of images to produce a 3-D visual model with characteristics analogous to that of actual features viewed using true binocular vision.”

In stereoscopic space perception, two major cues are used: the convergence and the binocular disparity. Convergence is the ability to focus the optical axes of the two eyes on to a single object. The sensing of the amount of muscular tension in the eyes resulting from different convergence angles provides a cue to the absolute distance to the viewed point. The binocular disparity (or parallax) is the disparity or the “difference” between the images of an object projected on to each retina. The degree of disparity between the two projected images depends on the convergence angle. The binocular disparity is considered the most important perception cue over medium distance, and is the only one used in stereophotogrammetry for quantitative elevation extraction.

The three main applications of stereoscopy are

1. as an interpretation aid in qualitatively recognizing the 3-D form of an object;
2. the quantitative estimation of slopes and relative heights; and
3. the quantitative and precise measurement of 3-D coordinates of planimetric and altimetric features.

In the last 50 years, first optico-mechanical and later analytical and digital 3-D photogrammetric systems capitalizing on the binocular parallax and convergence cues have been developed for aerial photographs to meet the needs of these three applications of stereoscopy (especially the last). It was Helava who developed the main concepts behind these analytical and digital systems in 1957. Most stereoworkstations have now been adapted to process stereodata from the same satellite sensors (space photo, VIR or SAR), but only a few can simultaneously process mixed sensor stereopairs. Stereopairs displayed on the screen are separated either spatially, radiometrically or temporally. Photogrammetric principles for space photographs (collinearity and coplanarity conditions) and their equivalent for remote sensing data mathematically solve the relationship between 2-D image coordinates and 3-D ground coordinates. The hardware and software to derive information from the 2-D digital imagery have thus allowed the mapping process to become more automated, but not completely, with occasional unmatched expectations.

Among all the new developments of stereoworkstations, DEM generation is an important R&D topic. In fact, any satellite data can be used to generate a stereoscopic pair and simulate the natural depth perception, as soon as the terrain is imaged from two different viewpoints. Since the stereoscopic methods to extract elevation, based on the binocular disparity and parallax, are “more or less” the same, stereoscopic capabilities of different sensors are first analyzed. The processing, the methods and the error propagation are then addressed.

#### 4.2 Visible and Infrared Sensors

Two main categories of VIR sensors have to be considered: space cameras and digital scanners.

##### 4.2.1 Space Cameras

For a long time, space camera technology remained in the military domain. Since the techniques and technologies of space photographs are derived from classical aerial photographs, photogrammetrists have postulated that space cameras would be the next logical step for topographic mapping.

The first significant satellite photogrammetry experiment was done using imagery on the Apollo 15, 16 and 17 missions to the moon. A lunar control net with a 30-m relative accuracy in the three coordinate axes was generated, and 1:25 000 topographic ortho-photo maps were produced. After a few early stereo hand-held photographs acquired during the Gemini and Apollo missions, the ETC experiment on board Skylab-D in 1974 produced the first along-track stereoviewing images from space. One of the first attempts to measure heights from space images was made by Mott. He reported an RMSE of 120 m for a strip of four Skylab models and concluded that the minimum contour intervals to be plotted should be approximately 250 m.

The ETC was followed by the German Democratic Republic’s MKF-6M multiband camera flown on the Soviet spacecraft Soyuz 22 and Salyut in 1976. None of these were metric cameras (MCs) capable of producing...
acceptable accuracy, even with an image pixel size of 17–30 m. Furthermore, wide spaces between ground tracks hindered the mapping of large areas.\(^{(9,52)}\)

In 1978, the USSR flew the KATE140 MC on Salyut, acquiring panchromatic images with 60-m resolution. Later, the USSR developed RESURS, a series of remote spacecraft based on the recoverable Vostok capsule. They carried different multiband MC (KATE-200, KFA-1000, LK-1000 and MK4) with retrievable film on missions lasting between 2 and 4 weeks. The ground resolution varied from less than 5 to 30 m. At the same time, the German Zeiss MC initiated by the European Space Agency (ESA) took panchromatic and near-infrared images during the Space Shuttle STS-9 mission between November 28 and December 7, 1983. Later, the ITEK Large Format Camera (LFC) initiated by the National Aeronautics and Space Administration (NASA) was flown on the Space Shuttle STS-41-G on October 5–10, 1989. The LFC has a Forward Motion Compensation (FMC) system to produce a better image quality.

Since these different MCs have along-track stereocapabilities, elevation can be derived. However, most of the research work has been on the estimation of the stereocentricity,\(^{(9,50,51)}\) or on the evaluation of planimetric and altimetric accuracies over a limited number of points.\(^{(53)}\) Other results were reported by various authors at the MC Workshop held in Oberpfaffenhofen, Germany, in February 1985, and at the ACSM–ASPRS Annual Meeting held in Washington, DC, in March 1986. They mainly used an analytical stereoplotter for which earth curvature correction has been added to the normal photogrammetric bundle adjustment, but not for varying atmospheric conditions.\(^{(54)}\)

Two experiments generated contour lines, one with MC data\(^{(55)}\) and the other with LFC data,\(^{(56)}\) both on analytical stereoplotters. In the first experiment, 50-m contour lines were digitally plotted and compared with 1:25 000 topographic maps. It shows a standard error of about 30 m with larger errors in the steepest areas. In the second experiment, difficulty in extracting 20-m contour lines was reported. The height accuracy of the extracted contour lines was only computed from 30 points, and was 15 m on average for stereopairs with a base-to-height (B/H) ratio of more than 0.6. Although less significant, these LFC stereopair results are better owing to the FMC system. The accuracy obtained was of the same order as the predicted accuracy for generating contour lines at 20–30-m intervals with LFC data,\(^{(50)}\) but it does not completely meet the requirements of cartography, particularly in mountainous areas.\(^{(52)}\)

The main reasons why these data have not been used for operational DEM production are as follows:\(^{(55)}\)

- the limited distribution of the data relative to the amount of acquired images;
- the experimental nature of the data and system, and the lack of decision to make it fully operational and repetitive; and
- the relatively poor quality of the data.

Consequently, the stereocapabilities of the MC and LFC have mainly become a source of planimetric feature content for mapping using traditional photogrammetric techniques with an analytical stereoplotter.\(^{(57)}\)

### 4.2.2 Digital Scanners

To obtain stereoscopy with images from satellite scanners, two solutions are possible:

1. along-track stereoscopy from the same orbit using fore and aft images; and
2. across-track stereoscopy from two different orbits.

The latter solution was the most used since 1980: first with Landsat from two adjacent orbits, then with SPOT using across-track steering capabilities and finally with IRS 1C/D by “rolling” the satellite. In the last few years, the first solution, as applied to space frame cameras, gained renewed popularity. Examples are, the Japan Earth Resources Satellite (JERS)-1 OPS, the German Modular Opto-electronic Multispectral Stereo Scanner (MOMS), the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), the IRS P5 and most of the high-resolution satellites such as Orb-View1 and Quick-Bird. Only Ikonos will have simultaneously along- and across-track capability.

#### 4.2.2.1 “Adjacent Orbit” Stereo

In the case of Landsat (either Multi Spectral Scanner (MSS) or TM), stereoscopic acquisition is only possible from two adjacent orbits since the satellite acquires nadir viewing images, and the tracking orbit ensures a repeat path consistent within a few kilometers. In fact, since the mean B/H ratio with Landsat MSS is around 0.1, one needs relief of about 4000 m to generate a parallax of five Landsat MSS pixels (80-m resolution). Owing to its quasipolar orbit, the coverage overlap grows from about 10% with a B/H ratio of 1.8 at the Equator to about 85% with a B/H ratio of 0.03 at 80° latitude. From 50° north and south the coverage overlap (45%) with a B/H ratio less than 0.12 permits quasioperational experiments for elevation extraction. Welch and Lo\(^{(58)}\) extracted the elevation of 10 control points from different color-photograph stereopairs acquired from Landsat-1. They designed a precise parallax-bar instrument with various viewing magnifications (10–30°), and obtained an RMSE for the elevation between 300 and 500 m. They noticed a
large error in the parallax difference measurements on the analog photographs. Digital processing should thus allow a better parallax measurement accuracy.

Simard\textsuperscript{59} and Simard and Slaney\textsuperscript{60} then used digital Landsat MSS and Landsat TM stereopairs, respectively with a $B/H$ ratio of 0.11 over the mountains (2000-m elevation variation) in British Columbia, Canada. Ehlers and Welch\textsuperscript{61} also applied the method using Landsat TM data with a larger $B/H$ ratio (0.17) over a low relief (500-m elevation variation). For the three experiments, the images are first corrected for the geometric distortions related to the platform, sensor and look geometry. The residual misregistration (or parallax) between the images of the stereopair thus reflects the relief effect. Cooper et al.\textsuperscript{62} also suggested correcting for the earth’s curvature, if it is not done. Since the east-west component accounts for almost 98% of the total parallax, a simplified one-dimensional model to compute the elevation from the measured parallax can be used (Equation 1):\textsuperscript{59}

$$dh(x, y) = dp(x, y) \frac{H}{B}$$

where $dh$ and $dp$ are the relative height and parallax at each image point $(x, y)$, respectively.

This equation can be modified for the different orientation of the scan lines, but the variation in $B/H$ is less than 0.004.\textsuperscript{61} These models are an approximation of the stereogeometry, which is only good because of the coarse satellite image resolution (30–80 m), the poor $B/H$ (0.1–0.2) and the final expected accuracy (50–100 m).

The parallax for each pixel is measured using a hierarchical cross-correlation technique with variable reference window size.\textsuperscript{59} The window size for the search window can also be adjusted according to image content and signal-to-noise ratio.\textsuperscript{61} More details on the method are given in section 4.5.

Qualitative and visual evaluation of the resulting DEM or the derived contour lines show generally good agreement when overlaid on the ortho-rectified Landsat MSS imagery\textsuperscript{59} or with the existing map contour lines.\textsuperscript{61} Quantitative evaluation gives an RMSE of about 45 m when compared with independent check points (ICPs),\textsuperscript{60,61} and of 60–70 m with a low-precision 1:250 000 map-derived DEM.\textsuperscript{62} The resulting variations of this last study can be accounted for by the low-precision map DEM and from the correlation process using edge matching instead of gray-level matching. More details on the correlation results and performances are given in section 4.5.

The stereoscopic capabilities with Landsat data still remain limited because:

- it generates a small $B/H$ ratio leading to elevation errors of more than 50 m; and
- only medium to high relief areas are suitable for generating sufficient vertical parallax.

4.2.2.2 “Across-track” Stereo To obtain good geometry for better stereoplotting, the intersection angle should be large in order to increase the stereoeaggration factor, or equivalently the observed parallax, which is used to determine the terrain elevation. According to Light et al.,\textsuperscript{63} $B/H$ ratios of 0.6–1.2 are a typical value to meet the requirements of topographic mapping. The SPOT system with its across-track steering capabilities ($\pm 26^\circ$) can generate such $B/H$ ratios. In conjunction with a finer pixel size (10 m for a panchromatic image), a more precise model has to be used to transform the parallax extracted from the raw SPOT images into an elevation value. Since the perspective of the SPOT push-broom scanner is a conico-cylindrical perspective (conical for imaging a line and cylindrical for the displacement of the satellite), new geometric and stereoscopic models, equivalent to colinearity and coplanarity equations in photogrammetry, have to be developed for the generation of a precise DEM. To transform image coordinates or parallax into map coordinates, the parametric model has to take into account:

- the distortions relative to the platform (position, velocity, orientation);
- the distortions relative to the sensors (orientation angles, instantaneous field of view, detector signal integration time);
- the distortions relative to the earth (geoid–ellipsoid including relief); and
- the deformations relative to the cartographic projection (ellipsoid–cartographic plane).

Some of the first studies were undertaken at the Institut Géographique National (IGN), France, from raw-type simulated stereo SPOT data generated by the Centre National d’Études Spatiales (CNES), the French Space Agency.\textsuperscript{64–66} These three studies reported a 3-m accuracy in both planimetry and altimetry with the simulated stereopair ($B/H$ ratio of about 1.1). Furthermore, 20-m contour lines were generated using automatic correlation, and qualitatively compared with contour lines generated from aerial photographs with an analytical stereoplotter.\textsuperscript{65} Quantitative results have also been presented using the Matra Traster analytical stereoplotter with the same simulated SPOT stereopair\textsuperscript{67} and showed an elevation error of 5 m with 80% confidence.

Simulation work on georeferenced-type SPOT data was also done in Canada and a DEM was generated with an RMSE of 5.7 m from geo-referenced stereomages corrected for systematic distortions (satellite, sensor,
earth’s curvature and rotation) with a $B/H$ ratio of 0.5. Other studies with simulated SPOT images were later conducted around the world (US, UK, Australia, Sweden, etc.) using analytical stereoplotter or automatic correlation methods.\textsuperscript{62,68}

After the launch of SPOT-1 in February 1986, CNES sponsored the SPOT Preliminary Evaluation Program (PEPS) to assess SPOT capabilities for thematic and topographic mapping. In preparation for the launch and early PEPS data, considerable research was carried out to develop robust and rigorous mathematical models describing the specific acquisition geometry of the SPOT–HRV sensors.\textsuperscript{64,69–76}

Most of these researchers used the photogrammetric solution (collinearity conditions for the conic perspective of a single image line) and took into account the displacement of the satellite (cylindrical perspective) to link the equations. Since the parameters of neighboring lines are highly correlated, and satellite positions and attitude can be computed from on-board recording systems, the mathematical equations can be reduced to a minimum of 8–10 unknowns depending on the development and implementation of the solution. Only some of them have been adapted to process stereodata (coplanarity condition).

Most of the results with real data were presented at the SPOT-1 Image Utilization, Assessment, Results Symposium held in Paris, in November 1987.\textsuperscript{77} Academic research results rather than operational systems or projects dominated the Symposium. In general, an accuracy of 10 m or less for the planimetry and the elevation was achieved. The differences are mainly dependent on the accuracy of the SPOT geometric modeling and its implementation in the workstation since good cartographic data were generally used. For DEM generation two main processing methods have been presented:

- using an analytical stereoplotter or
- using a digital image analysis system.

The first method uses a stereoanalysis system with SPOT data on transparency photographs. Following the Traster System developed by Matra in conjunction with IGN, France, for the software aspects,\textsuperscript{67} different universities or mapping agencies around the world developed solutions in collaboration with photogrammetric instrument manufacturers: the Kern DRS-1,\textsuperscript{78} the Zeiss Planicomp,\textsuperscript{79,80} the Wild Aviolt\textsuperscript{81} and the Canadian NRC Anaplot-1.\textsuperscript{82} Contour lines can be interactively stereoplotted to further generate DEM. Petrie\textsuperscript{83,84} provided useful information on the progress of analytical stereoworkstations and their processing capabilities. Later, Hottier and Albattah\textsuperscript{85} described a method by resampling raw SPOT stereograms to generate a pair of quasi-epipolar images that is suitable for stereoplotting on an analog stereoplotter. The processed stereoimage pair was plotted on a Wild AG1 without either excessive $Y$-parallax or significant loss of information.

When digital photogrammetric workstations became more available, the different analytical solutions and software were ported into these fully digital systems. Some of them also took advantage of low-cost personal computers.\textsuperscript{86–88} Dowman et al.,\textsuperscript{89} Heipke\textsuperscript{90} and Walker and Petrie\textsuperscript{91} are useful sources of information on the progress of digital stereoworkstations and their processing capabilities.

The second method uses fully digital images and processing without any stereoviewing capabilities most of the time. The DEM is automatically derived from the digital SPOT images using correlation techniques and a geometric SPOT model.\textsuperscript{92–96}

The IRS 1C and 1D also have cross-track stereocapability. This is achieved by rolling the satellite rather than steering the instrument. In anticipation of the planned stereo IRS 1C data, Malleswara et al.\textsuperscript{97} used the "adjacent orbit" stereotechnique with the IRS 1A linear imaging self-scanning sensor data, which does not have across-track stereocapability. Using the same methodology with Landsat data (geo-referenced data, least-squares matching and approximated elevation modeling) they generated a DEM over three study sites with stereograms displaying various overlaps (16–27%) and $B/H$ ratios (0.12–0.14).

The DEMs were then checked with 30 ICPs, and showed an error with 90% confidence of about 35 m with a slight correlation between the error and the $B/H$. Jacobsen\textsuperscript{98} carried on the investigation with three IRS 1C images (two off-nadir, $B/H = 0.8$, and one nadir) over Hannover, Germany. When compared with over 80 ICPs he obtained an accuracy of $\pm1.1$ pixels (6.5 m) in planimetry and elevation. No DEM was extracted. The results are worse than those generally obtained with SPOT or with other IRS 1C data because:

- he used a nonparametric solution instead of using a rigorous photogrammetric solution adapted to the specific geometry and characteristics of the LISS sensors;\textsuperscript{99,100} and
- the attitude data are not always consistent and accurate.\textsuperscript{101}

Few results on DEM extraction have been published, owing to the limited availability of stereo IRS images. Cheng et al.\textsuperscript{101} generated a DEM (least-squares matching, rigorous photogrammetric modeling) from raw IRS 1C LISS stereograms ($B/H = 0.52$) over a mountainous area in Arizona, USA (elevation variation of 2100 m). They reported an elevation accuracy of about 10 m when compared with both ICPs and digital DEM of the United
States Geological Survey (USGS). It is still worse (1.7 corresponding pixels) than results on the same type of relief with SPOT (about one corresponding pixel or better). This is most likely due to the inconsistent attitude data. Further work with IRS 1D could provide a better answer if stereodata were more available to researchers.

4.2.2.3 “Along-track” Stereo Launched in 1992, JERS had the capability to acquire along-track stereomages by the use of forward and nadir linear array sensors, named OPS. The 15° forward-looking image and the nadir-looking image (18-m ground resolution) generate a stereopair with a B/H ratio of 0.3. The simultaneous along-track stereodata acquisition gives a strong advantage in terms of radiometric variations versus the multidate across-track stereodata acquisition. This was confirmed by the very high correlation success rate (82.6%), which can compensate for the weaker stereogeometry.

Few results on DEM extraction from JERS data have been presented after the first Japanese experiment. All experiments have generated DEMs with the correlation method and photogrammetric solutions. Although the methods used are approximately the same, Westin obtained results (20 m) twice as good as Maruyama et al. or Raggam and Almer. This 20-m accuracy corresponds to one pixel spacing, which needed an automatic parallax measurement accuracy of better than one-third of a pixel with a 0.3 B/H ratio. Even when the GCPs were separated from over a 200-km distance on the same image strip, the interpolated distance and the distribution of the control data did not affect the elevation accuracy.

The German MOMS is another push-broom scanner with along-track stereocapability. This development started with MOMS 1 in 1979, with the first experiment flown mainly as a technical verification of the instrument line. In a second step, experimental MOMS 2 data (ground resolution of 13.5 m) were acquired during the German space laboratory mission in 1993 for testing the map generation potential. Since the system has fore-and-aft scanners, a B/H ratio of 0.8 can be obtained. Both methods, with an analytical plotter and with digital correlation, have been used over an Australian test site to produce 10- and 5-m intermediate contour lines and DEMs, respectively. Checked only with ICPs, a DEM error of 16 m was measured. Qualitative evaluation of the contour lines achieved very good consistency (even for the 5-m contour lines) with the ground truth. It thus makes sense to 1: 25 000 to be mapped. These better results are accounted for by the superiority of human depth perception when compared with automatic correlation techniques with this data set. Owing to the bad quality of the control data in the Australian data set, they expected to improve consistently the height accuracy to 5 m with the third MOMS 2P/PRIORODA mission to be flown on the Russian space station MIR. However, the first experiment with these third mission data (18-m resolution and 0.8 B/H ratio) showed a degradation of the DEM accuracy to 25–30 m while a second experiment achieved a 10-m accuracy. The large discrepancy between these last two experiments can be accounted for by the different type of relief and/or by the different geometric modeling of the 3-D array scanner. Future studies will confirm the potential accuracy of this VIR scanner.

4.3 Synthetic Aperture Radar Sensors

In the 1960s, stereoscopic methods were first applied to radar images to derive ground elevation leading to the development of radargrammetry. It was shown that some specific SAR stereoconfigurations would produce the same elevation parallaxes as those produced by air photographs. Consequently, elevation could be derived on traditional stereoplotters. They can only be used to measure target elevations. Furthermore, Carlson developed a single-path technique to generate radar stereomages, which made it easier to view and to measure parallax for elevation computation than the traditional two-path technique. However, the lack of radar stereopairs led mainly to theoretical studies or simulated data processing experiments.

During the 1980s, improvements in SAR systems, with parallel investigations into the theory, allowed the demonstration of stereoradar with same-side or opposite-side viewing. These theoretical studies and practical experiments confirmed that the opposite-side stereocofiguration is superior to the same-side stereoconfiguration. The difficulty in using these geometrically superior configurations stems from the illumination differences that are too pronounced to be stereoscopically viewed and the difficulty of finding corresponding points and features. Figure 1 illustrates the intersection geometry with the radar parallax due to elevation for different stereocofigurations (same versus opposite side; steep versus shallow look angles).

To obtain a good geometry for better stereoplotting, the intersection angle (Figure 1) should be large in order to increase the stereoexaggeration factor, or equivalently the observed parallax, which is used to determine the terrain elevation. Conversely, to have good stereoviewing, the interpreter (or the image matching) prefers a stereopair as nearly identical as possible, implying a small intersection angle. Consequently, large geometric and radiometric disparities hinder both stereoviewing and precise stereoplotting. Since the reduction of one disparity could compensate for the other disparity, a compromise
remotely sensed has to be reached between better stereoviewing (small radiometric differences) and a stronger geometry and plotting (large parallax).

The common compromise for any type of relief is to use a same-side stereopair, thus reducing both disparities. Unfortunately, this does not optimize the full potential of stereoradar for all terrain topography. A compromise to reduce the radiometric difference of an opposite-side stereopair is to invert the radiometry of one image. When processing digital images, Fullerton et al. added a local brightness change to exclude some image features from the radiometric inversion. A low frequency or a sparse DEM can also be used to reduce the geometric disparity, as applied with success to iterative hierarchical SAR image matching. Another potential compromise is to use an opposite-side stereopair over rolling topography. The rolling topography reduces the parallax difference and also the radiometric disparities (no layover, shadow and little foreshortening), making possible stereoviewing and good stereoplotting.

However, with spaceborne platforms, parallel flights (from the opposite or same side) are very rare. Even sun-synchronous satellite orbits are only parallel near the Equator. Elsewhere, crossing flight lines or convergent stereoconfigurations must be considered. No differences exist between computations for parallel flight lines and those for crossing flight lines if rigorous intersection geometry is applied. This was confirmed with the Spaceborne Imaging Radar (SIR) A and B shuttle missions of 1981 and 1984. The last two studies processed radar photographs on an analytical stereoplotter, the Kern DSR-1, which was adapted to process stereo SAR images. The first study used a fully digital method with iterative hierarchical matching. The results achieved for the DEM were of the order of 60–100 m, due mainly to the poor SIR A resolution or radiometric and geometric image quality. Furthermore, with the SIR B SAR system, stereopairs with intersection angles ranging from 5° to 23° can be created. Since the launch at the beginning of the 1990s of different satellite sensors (Almaz, ERS, JERS, etc.) radargrammetry again became a “hot” R&D topic. First, the Russian Almaz-1 SAR system could have acquired images with different angles to obtain stereocimages in the latitude range 0–72°. Yelizavetin digitally processed two images with 38° and 59° look angles acquired over a mountainous area of Nevada, USA. No quantitative results were given. Stereocopy with ERS–SAR data is achieved using an image with its normal look angle (23°) and a second image with the roll–tilt mode angle (35°) to generate a same-side stereopair. It can also be done with two normal look angle (23°) images from ascending and descending orbits to generate an opposite-side stereopair. Comparison of these research results, 20 versus 40 m, confirmed

![Figure 1](image-url) The intersection geometry with the radar parallax (p) due to the terrain elevation (h) for different stereo SAR configurations (same side versus opposite side; step versus shallow look angles). (Courtesy of the Canada Centre for Remote Sensing, Natural Resources Canada.)
the superiority of the opposite-side stereopair. With the JERS–SAR, stereoscopy has been achieved with adjacent orbits generating a small overlap with a small intersection angle. The digital correlation method was used to generate a 75-m accurate DEM.

Results obtained with simulated and spaceborne SAR data can be summarized as follows:

1. Kaupp et al. found that the optimum intersection angles are about 40–45°;
2. Domik showed that the best subjective stereoimpressions were obtained with shallow look angles (50–70°), and at an intersection angle of 20°;
3. Leberl et al. showed that the highest accuracy is not necessarily achieved with the largest intersection angles;
4. Fullerton et al. noted that higher ground resolution does not necessarily lead to higher height accuracy; and
5. better accuracy is more consistently achieved with an opposite side stereopair.

These reported results are inconsistent and practical experiments do not clearly support theoretical expectations: for example, larger intersection angles and higher spatial resolution do not translate into higher accuracy. In various experiments, accuracy trends even reverse, especially for rough topography. Only in the extreme case of low relief does accuracy approach theoretical expectations.

By analogy with photogrammetry, theoretical error analyses were first developed by Rosenfield and La Prade. They related an error of an exterior orientation element in the left and right images to the resulting error in the stereomodel. These first analyses were mainly limited to absolute errors regardless of the stereoconfiguration. As a summary, an estimation of the error in the cross-track and elevation coordinates, $E_x$ and $E_h$, respectively, due to an error in range, $E_r$, for the measurement of a target in the stereomodel is given by Equations (2) and (3):

$$E_x = \frac{(\cos^2 \theta_L + \cos^2 \theta_R)^{1/2}}{\sin \Delta \theta} E_r$$

$$E_h = \frac{\sin \theta_L + \sin \theta_R}{\sin \Delta \theta} E_r$$

where $\theta_L$ and $\theta_R$ are the look angles of the left and right images, respectively, and $\Delta \theta$ is the intersection angle, i.e. the difference between the two look angles.

As shown in Equations (2) and (3), the error modeling accounts only for SAR geometric aspects (look and intersection angles, range error) and completely neglects the radiometric aspects (SAR backscatter) of the stereopair and of the relief. This error propagation modeling can then only be applied when the radiometry has a minor role and impact with respect to the geometry, such as during the stereomodel set-up with GCPs, which are radiometrically well-defined points. The residuals of the least-squares adjustment of the stereomodel are thus correlated with the intersection angle.

Since SAR backscatter and consequently the image radiometry are much more sensitive to the incidence angle than the VIR reflectance, especially at low incidence angles, the theoretical error propagation has a major limitation as a tool for predicting accuracy and selecting appropriate stereoimages for DEM generation. Care must therefore be taken in attempting to extrapolate VIR stereococepts to SAR.

Before RADARSAT, Canada’s first earth observation satellite, was launched in November 1995, it was difficult to acquire different stereoconfigurations to address this point precisely, namely the impact of radiometry in the error propagation. RADARSAT (Figure 2) with its operating modes of RADARSAT SAR. (Courtesy of the Canadian Space Agency.)
various operating modes, imagery from a broad range of look directions, beam positions and modes at different resolutions fills this gap. Under the Applications Development and Research Opportunity (ADRO) program sponsored by the Canadian Space Agency (CSA), researchers around the world have undertaken studies on the stereoscopic capabilities by varying the geometric parameters (look and intersection angles, resolution, etc.). Most of the results were presented at the final RADARSAT ADRO Symposium held in Montreal, Canada in 1998.

There was general consensus in the results of the DEM extraction accuracy: slightly more than one resolution for the fine-mode (12 m), and slightly better for the standard mode (20 m), whatever the method used (digital stereoplotter or image correlation). Relative elevation extraction was also addressed from a fine-mode RADARSAT stereopair for the measurement of canopy heights in the tropical forest of Brazil. However, there was no significant correlation between the DEM accuracy and the intersection angle or the vertical parallax ratio. In fact, most of the results showed that the principal parameter that has a significant impact on the precision of the DEM is the type of the relief (and its slopes). The greater the variation between two look angles (e.g. 23° and 47°), the more the quality of the stereoscopic fusion deteriorated. This cancels out the advantage obtained from the stronger stereogeometry. On the other hand, although a higher resolution (fine mode) produces a better quality image, it does not change the stereocuracy for a given stereocollection (e.g. intersection angle) and it does not significantly improve the DEM accuracy. Furthermore, although the speckle creates some confusion in the stereoplotting, it does not degrade the DEM accuracy because the correlation method or the human stereoviewing “behaves like a filter”. Preprocessing the images with an adaptive speckle filtering does not improve the DEM accuracy; it can slightly reduce the image contrast and smoothes the relief (especially the low relief).

Since the type of relief is an important parameter in the DEM accuracy, it is strongly recommended that the DEM accuracy be ascribed values that reflect the different areas of the relief. Furthermore, in the choice of a stereoscopic pair for DEM generation, both the geometric and radiometric characteristics must be jointly evaluated taking into account the SAR and surface interaction (surface geometry, vegetation, soil properties, geographic conditions, etc.). The advantages of one can compensate for the deficits of the other.

### 4.4 Mixed Sensors

Owing to the increasing amount of image data, it is very common to have data from different sensors over the same terrain area. The traditional stereoscopic technique can thus be applied. By perceiving the different radiometry in the brain, the stereoscopic fusion of mixed sensors can also provide a virtual 3-D model of the terrain surface. Few results have been published on the use of mixed stereosensors to generate DEMs. Welch et al. used a 23° viewing angle SPOT image (band 3) and a Landsat TM image (band 4) with the automatic stereocorrelation capability of the Desktop Mapping System. Comparison of profiles for the stereextracted DEM with the existing 1:50 000 topographic maps indicated an RMSE of about ±100 m. This large error is mainly due to the polynomial coregistration process instead of a rigorous parametric geometric model. In fact, Raggam and Almer generated a 50-m accurate DEM from a 23° viewing angle SPOT image (band 1) and a Landsat TM image (band 2). A proper relative registration process was used to generate the epipolar images for the measurement of corresponding image points with an automatic stereocorrelation process. They reported a 65% success rate in the correlation step due to the radiometric difference between the two images and to the homogeneous nature of some areas (snow fields, glacier or shadow). Human interaction is still required to reject blunders or to fill the mismatched areas in order to optimize the DEM results. This requires a digital stereoworkstation, not only with automatic matching, but also with full stereoscopic capabilities (GCP and tie points stereoplotting, 3-D DEM editing, 3-D cartographic feature extraction, etc.).

In fact, the brain can generate the perception of depth combining, for example, the spatial information from a SPOT panchromatic image and the spectral information from a Landsat TM image for stereoplotting when image matching fails. Toutin reported an altimetric accuracy of 37 m for the elevation data extracted from a raw 26° viewing angle SPOT P and Landsat TM (band 1) stereopair. The 10-m resolution of the SPOT P image, and the fact that elevation data are extracted directly from the raw image (no polynomial coregistration or epipolar image resampling), account for the better results. More difficulties have been reported by Akeno when trying to generate a DEM from a National Oceanic and Atmospheric Administration (NOAA)/Advanced Very High Resolution Radiometer (AVHRR) and Landsat MSS stereopair owing to the large resolution difference (1 km versus 80 m). He registered the two images using image-to-image correlation and degraded the Landsat MSS image to the AVHRR resolution. He reported 320-m accuracy over the good matched DEM points. The main difficulty was to obtain the sub-pixel accuracy in the correlation process, applied in the NOAA/AVHRR image rectification and the parallax measurement.
When two optical images are not available, a stereopair can be generated and viewed by combining optical and SAR images. Moore (142) first addressed the principle theoretically. He used simultaneously acquired infrared line-scanner and SAR images. In neither case was the visual stereoscopic effect perfect except near a 45° viewing angle. Various scaling factors were also applied to different areas of the stereopair to obtain the proper stereoscopic effect for the height determination. No quantitative measurement was achieved owing to the lack of an “adapted” stereoplotter.

Further evaluation was done with SIR B and Landsat TM images. (143) Only moderate results over 27 extracted points were reported, mainly due to pixel offset error in the registration of the images and the approximated angular values used in the simplified elevation computation equation. Using a better parametric solution, Raggam et al. (144) extracted a DEM from a multiband SPOT and airborne SAR stereopair. Since no meaningful results can be obtained from automatic image correlation, they interactively measured 500 corresponding image points and computed the elevation off-line. Results of the comparison with a reference DEM showed a standard deviation of 60 m with a 42-m bias and minimum/maximum errors of about ±250 m. More recently, Toutin (145) further investigated the mapping feasibility of mixed sensor stereopairs with parametric geometric solutions ported into a fully digital stereoworkstation adapted to process on-line VIR and SAR stereopairs. From the raw images (no epipolar resampling), the data are interactively stereoextracted and then directly compared with a checked DEM. An accuracy of 20 m with no bias and minimum/maximum errors of less than ±100 m has been achieved from two different SPOT-P and ERS–SAR stereopairs, one being an opposite-side stereopair and the other a same-side stereopair. The full on-line stereocapabilities in the GCPs plotting and elevation measurements account for the good results. Comparisons of the two stereopair results showed that the elevation parallax, which contributes to the determination of the elevation, is mainly dominated by the SAR geometry with its high sensitivity to the terrain relief. Conversely, the radiometry of the SPOT-P images mainly contributes to the determination of the features with the quality of the image content.

### 4.5 Processing, Methods and Errors

The different processing steps to produce DEMs using stereoimages can be described in broad terms as follows:

1. to acquire the stereoimage data with supplementary information such as ephemeris and attitude data if available;
2. to collect GCPs to compute or refine the stereomodel geometry;
3. to extract the elevation parallax;
4. to compute the 3-D cartographic coordinates using 3-D stereointersection; and
5. to create and post-process the DEM (smoothing, filtering, 3-D editing, etc.).

Steps 2 and 4 involve mainly geometric issues and step 3 involves radiometric issues while steps 1 and 5 involve both geometric and radiometric issues. Since the stereomodel geometry computed from the GCPs and step 4 are related and dependent on the type of images, they are addressed in step 1.

#### 4.5.1 Acquiring Stereoimage Data

With VIR images two types of data can be used: raw images with only normalization and calibration of the detectors (e.g. level 1A for SPOT), or geo-referenced images (e.g. level 1B for SPOT) corrected for the systematic distortions due to the sensor, the platform and the earth’s rotation and curvature.

Raw 1A imagery is preferred by photogrammetrists for use in analytical or digital stereoworkstations. As mentioned previously, the geometric modeling solution employs the well-known colinearity and coplanarity equations. They have been adapted to suit the geometry of scanner imagery, but also have benefited from theoretical work in celestial mechanics to determine better the satellite’s osculatory orbit and parameters (146, 147). More details on the development of the solutions and their implementation in the workstations can be found in the different referenced papers.

Since they have been systematically geo-referenced, the “level 1B” images just retain the elevation parallax. To compute the cartographic 3-D coordinates (step 4), the 3-D stereointersection modeling is then reduced with a simpler 2-D polynomial-based solution for the planimetry, and separately with a simple parallax equation solution for the elevation (Equation 1). This method was mainly applied in the first experiments with Landsat (59–62) since the approximation generated by the method is smaller than the final expected accuracy. However, with SPOT stereoimages (better resolution and larger B/H ratio), the approximation is no longer valid and generates poorer results than with “raw” stereoimages. (78, 148)

The solution to overcome this approximation when using 1B stereoimages is to convert the 1B images back into 1A images using the reverse transformation (149) or to “reshape and resize” the 1B images to the raw imagery format (150). This 1B geometric modeling can be mathematically combined with the normal 1A geometric modeling to avoid multiple image resampling. Although this mathematical procedure used for 1B stereoimages works better than the simple parallax approximation, it
is still recommended that raw stereomages with the rigorous parametric solution (collinearity and coplanarity equations) be used.

The SAR images are standard products in slant or ground range presentations. They are generated digitally during postprocessing from the raw signal SAR data (Doppler frequency, time delay). The ground range presentation is the most popular product since the pixel spacing on the ground is roughly the same for the different look angle images. It then facilitates the stereoviewing and matching. The geometric modeling solution to compute the stereomodel and 3-D intersection starts generally either from the traditional Doppler and range equations,\textsuperscript{128,131} from the equations of radargrammetry\textsuperscript{14} or from generalized equations.\textsuperscript{129} Their mathematical developments are different, and also depend on the method used (e.g., analytical or digital stereoworkstation, digital image or visual matching).

\subsection*{4.5.2 Collecting Ground Control Points}

Whatever the VIR and/or SAR geometric modeling used for the stereomodel and 3-D intersection, some GCPs have to be acquired to refine the stereomodel with a least-squares adjustment process in order to obtain a cartographic standard accuracy. Since the polynomial modeling does not reflect the geometry of viewing, it requires many GCPs (20 and more) spread over the full stereopair. Each image modeling is computed separately, which does not set up a relative orientation between the images. Furthermore, the elevation is computed from an approximated solution. Consequently, this modeling cannot be used to provide the high cartographic accuracy required with the latest generation of satellites such as SPOT, IRS, MOMS, ERS and RADARSAT.

With parametric modeling such as those defined previously, few GCPs (1–6) are required. In an operational environment their number will vary as a function of their accuracy. They should preferably be spread at the border of the stereopair to avoid extrapolation in planimetry. It is also preferable to cover the full elevation range of the terrain. Different types of GCPs can be used:

- full control points with known XYZ coordinates;
- altimetric points with known Z coordinate; and
- tie points with unknown cartographic coordinates.

The two last types are useful to reinforce the stereogeometry and fill in gaps where there is no XYZ GCP. Furthermore, GCPs displayed only on one image in or outside the stereopair can also be acquired as complementary points to the “stereo” GCPs. Combined with tie points they can also help to avoid extrapolation in planimetry in areas where there is no “stereo” GCP.

The final accuracy of the stereogeometry is mainly dependent on the GCP’s cartographic and image coordinates. The first can be obtained from a global positioning system (GPS), air photographic surveys, map digitizing, etc. The image coordinates are plotted interactively on the plotter or the screen. Since some workstations do not have full stereoscopic capabilities, the image coordinates are obtained simultaneously in “double monoscopy”. This plotting will then create artificial X- and Y-parallaxes (few pixels) between the images, and the parallax errors will propagate through the stereomodel (relative and absolute orientations), the stereointersection and finally the DEM. The error propagation is much larger with a SAR stereopair than with a VIR stereopair where the plotting accuracy is about 1/3 pixel and $B/H \approx 1$. Owing to the same-side geometry with small intersection angles ($8^\circ$–$20^\circ$) of SAR stereopairs, this error propagation due to the “double monoscopic” plotting increases with shallower look angles and smaller intersection angles.\textsuperscript{132} Consequently, the DEM accuracy can decrease with a 20–40\% ratio, depending on the stereopair geometry.\textsuperscript{135} True stereoscopic plotting using human depth perception permits a better relative correspondence of the GCP between the images (SAR but also VIR) and a better absolute positioning on the ground. It is also a requisite that the two images are computed together, and not separately, to obtain a relative orientation between them.

\subsection*{4.5.3 Extracting Elevation Parallax}

Two main methods can be used to extract the elevation parallax using image matching: the computer-assisted (visual) and automatic methods. These two methods can, of course, be integrated to take into account the strength of each one.

The computer-assisted visual matching is an extension of the traditional photogrammetric method to extract elevation data (contour lines) on a stereoplotter. It requires full stereoscopic capabilities to generate the on-line 3-D reconstruction of the stereomodel and the capture in real time of 3-D planimetric and elevation features. For elevation, the contour lines or an irregular grid DEM can be generated. The stereoscopic viewing is completed on the computer screen using a system of optics. The stereomages are separated spatially, radiometrically or temporarily. Spatial separation is achieved using two monitors or a split screen and an optical system using mirror and/or convex lenses. Radiometric separation is achieved by anaglyphic or polarization techniques with colored or polarized lenses, respectively. Temporal separation is achieved by an alternate display of the two.
images and special synchronized lenses. Petrie,(84) Dow-
man et al.,(89) Audet and Lapierre,(151) Heipke(90) and
Walker and Petrie(91) presented the latest developments
in analytical and digital stereoworkstations over the last
20 years. Furthermore, Makarovic(152) gave a comprehen-
sive comparison between analytical and digital techniques
and systems.

To retain real 3-D performance in a stereoworkstation,
the images are resampled into an epipolar or quasi-
epipolar geometry, in which only the X-parallax related
to the elevation is retained.(69,153) Another solution to
control the image positioning from the raw imagery
is to follow automatically the dynamic change by
cancelling the Y-parallax using the previously computed
stereomodel.(97,129) In the same way as with a conventional
stereoplotter, the operator cancels the X-parallax by
fusing the two floating marks (one per image) on
the ground. The system then measures the 2-D parallax
between the images for each point and computes the
XYZ cartographic coordinates using the 3-D intersection.
The visual matching then combines in the brain a
geometric aspect (fusing the floating marks together)
and a radiometric aspect (fusing the floating marks on
the corresponding image point). Some automatic tasks
(displacement of the images or cursors, prediction of the
corresponding image point position, etc.) are added.

However, computer-assisted visual matching, princi-
ually used with paper-format images and analytical
stereoworkstations, is a long and expensive process to
derive a DEM. When using digital images automated
image matching can therefore be used. Since image
matching has been a lively research topic for the last
20 years, an enormous body of research work and litera-
ture exists on stereomatching of different VIR and SAR
sensors.

Most of the research studies on satellite image matching
are based on Marr’s research at the Massachusetts
Institute of Technology (MIT) into the modeling of
human vision.(154) If a computer program can be realized
to see things as a human would, then the algorithm
must have some basis in human visual processing. The
stereodisparity is based on “correct” assumptions about
the real world:(155) (i) a point of the surface has a unique
position in space at any one time and (ii) matter is
cohesive. The first generation of image matching based
on these assumptions is gray-level image matching. Gray-
level matching between the two images really implies
that the radiometric intensity data from one image,
representing a particular element of the real world, must
be matched to intensity data from the second image,
representing the same real-world element.

Although a satellite image of the real world represented
by gray-levels is not like a random-dot stereogram (easily
matchable), gray-level matching has been widely studied
and applied to remote sensing data. Most of the matching
systems operate on reference and search windows. For
each position in the search window, a match-value is
computed from gray-level values in the reference window.
The local maximum of all the match-values computed
in the search window is the good spatial position of
the searched point. The match-value can be computed
with the normalized cross-correlation coefficient,(59) the
sum of mean normalized absolute difference,(156) the
stochastic sign change or the outer minimal number
estimator, etc. The first approach is considered to be
the most accurate(157) and is widely used with remote
sensing images. It was also noticed that matching errors
were smaller with SPOT images and digitized aerial
photographs than with SAR images. The last two match-
value computation methods have rarely or never been
used by the remote sensing community.

Another solution to the problem of matching, intro-
duced by Förstner,(158) is the least-squares approach,
minimizing the squares of the image gray-level differ-
ences in an iterative process. This method makes possible
the use of well-known mathematical tools and the esti-
mation of the error. Rosenholm(159) found that the more
complicated least-squares method applied on simulated
SPOT images did not give any significant improvement
when compared with the cross-correlation coefficient.
However, this least-squares method seems to be more
accurate with real SPOT data.(7) No attempts have been
made with SAR images.

The notion of least-squares matching in the object
domain (ground) rather than in the image domain was
later introduced by Helava.(160) Predicted image densities,
corresponding to each ground element “groundel”,
are mathematically computed with known geometric
and radiometric image parameters, and matched to
the original one. The uncertainty in the parameters
of a particular groundel is resolved by least-squares
calculation. An advantage of this approach is the use
of more than two images from the same or different
sensors to make the least-squares solution meaningful,
and a disadvantage is the ability to model correctly the
groundel attributes for each image. It is mainly used with
air photographs since more than two images overlap the
same ground area and their geometry and radiometry are
better controlled.

Since one of the constraints was either missing or
incorrectly implemented in gray-level matching, Marr
developed a second generation of image matching:
feature-based matching.(161) The same element of the real
world may look considerably different in remote sensing
images acquired at different times and with different
geometries between the sensor, the illumination and the
terrain. Instead, edges in the images reflect the true
structures.(62) Feature-based matching has not been very

ELEVATION MODELING FROM SATELLITE DATA
popular in the remote sensing community, but successful applications have been achieved with simulated SPOT and Landsat TM.\(^{63}\) The DEM results were not as good as those obtained by Simard and Slaney\(^{60}\) with Landsat TM stereopairs using gray-level matching. Hähn and Förstner\(^{162}\) also found that least-squares matching is more accurate than feature-based matching, conversely to Marr’s theoretical prediction.

Hybrid approaches can be thus be used to achieve better and faster results by combining gray-level matching, feature-based matching with a hierarchical multiscale algorithm and also computer-assisted visual matching. The feature-based approach may produce good results for identified features, but no elevation at intermediate points. These results can then be used as seed points for the gray-level matching. Another hybrid approach is to generate gradient amplitude images as a first step with gray-level values derived from the original stereoimages instead of gradient images with only binary edge values.

In a second step, any gray-level matching technique can be used on these preprocessed images.\(^{163}\) The linear gradient operator can be designed to be optimal to remove noise (such as the SAR speckle) and to enhance edges. The first preliminary results with SAR stereopairs showed a 10–15% improvement in the DEM reconstruction, not always significant or consistent, but at least with fewer blunders, owing to the noise removal.

Although the computer-assisted visual matching is a long process, it has been proved to be more accurate with photographs or VIR data\(^{105,144}\) and with SAR data.\(^{134,144,156}\) It can therefore be used either to eliminate the blunders or to fill the mismatched areas or in areas where the automated image matching gives errors larger than one pixel (about 10% for SPOT, 15% for digitized photographs and 40–50% for SAR images\(^{157}\)). It can also be used to correct the lake elevations or to generate seed points for automatic matching.

Other developments tested principally for airborne images, but rarely with satellite images, include the global approach, scale space algorithms, relational matching, consideration of corresponding structures\(^{164}\) or of uniform regions,\(^{165,166}\) a moment-based approach with fine-invariant features\(^{167}\) or a wavelet transform approach.\(^{168}\) They were only used to extract well-defined GCPs for image registration between different spaceborne VIR images.

More development could be done to integrate these solutions for generating seed points to gray-level matching. Some apparent contradictions should also be the issue of future research studies, such as:

- the theoretical prediction of Marr\(^{154}\) that feature-based matching is better than gray-level matching versus better experimental results with gray-level matching than with feature-based matching;
- the theoretical automated image matching error (much better than one pixel) versus the experimental results (one and more depending on the data); and
- the “so-called” superiority of computer matching over the visual matching versus the experimental results.

These overall comments confirm our first statement that image matching has been a lively research topic for the past 20 years and it may be for the next 20 years!

5 OTHER METHODS

5.1 Interferometry

Radar interferometry is an alternative to the conventional stereoscopic method for extracting relative or absolute elevation information. It uses the advantages of SAR systems and of digital image processing: all-weather, night and day capabilities and automated or semiautomated processing. Imaging radar interferometry combines complex images recorded either with two antennas at different locations or with the same antenna at two different times. The phase difference information between the SAR images is used to measure changes in the range, on the subwavelength scale, for corresponding points in an image pair. By analyzing the phase variations, these distances can be translated into elevation or displacement on the ground. Since the interferometric techniques are largely detailed in another article (see Elevation Modeling and Displacement Mapping using Radar Interferometry) only the basic aspects are given here for understanding and comparing them with previously developed methods.

The first proposal and experiments in radar interferometry were in the field of planetary mapping in the context of radar astronomy.\(^{169}\) They used an earth-based range-Doppler system to map Venus, and the interferometric information was used only to resolve the ambiguity in the mapping of southern and northern hemispheres. The first airborne application was done by Graham\(^{170}\) with two antennas carried on an aircraft. “Classified” until 1980, the technique was later extended to SIR B data acquired from two separate passes acquired over several days.\(^{171}\) After the launch of ERS 1 in 1991, numerous multipass satellite interferometric studies have been accomplished,\(^{172,173}\) subsequently with Almaz-1\(^{174}\) and with RADARSAT.\(^{175}\) With existing satellite SAR data, only the repeat-pass system (one satellite antenna and two passes) can consistently generate interferometric data through the combination of complex images since there
is at present no satellite system with two antennas. Dual-antenna system data are only available from the 10-day Shuttle Radar Topography Mission (SRTM) realized in February 2000.

The images are registered and the phase difference is computed for each pixel. The main product is the interferogram (phase difference), and the secondary product is a coherence image, which indicates the correlation between the two SAR images. The phase difference, which is related to the two-way path difference of the radar echoes, is only known with a $2\pi$ ambiguity. It is then necessary to “unwrap” the phase differences for the determination of the absolute interferometric phase to within a constant.\(^{1,176}\) The terrain elevations can thus be derived using an accurate SAR imaging model. However, there are geometric and radiometric limitations in the computation of the terrain elevation since the phase difference contains several components: topographic, atmospheric, displacement and noise.

To resolve these ambiguities and to address these different components, different developments in SAR interferometric processing took place, first with airborne SAR data in the 1980s and later with spaceborne. These include:

- the impact of the interferometric baseline on the elevation accuracy;\(^{1,177}\)
- the evaluation of different atmospheric phenomena and the way to characterize them;\(^{1,178}\)
- the differential interferometry combining multiple interferograms to estimate subcentimeter surface displacement;\(^{1,179}\)
- the time interval between the image acquisitions.\(^{1,180}\)

Current developments also include the use of satellite radar interferometry to study dynamic phenomena and their relative elevation displacement. Combining a SAR interferogram generated from two ERS 1 SAR data acquired before and after an earthquake with a DEM, the topographic component is removed from the interferogram, and the displacement field of an earthquake is mapped.\(^{1,181}\) Topographic and displacement components can also be separated by combining three radar images to generate two interferograms.\(^{1,173}\) The estimation of the displacement field using radar data alone, without any terrain information, is then possible. Similarly, using repeat-track interferometry with a very small cross-track baseline, which generates an interferogram with little sensitivity to topography (small topographic component), Goldstein et al.\(^{1,182}\) measured and estimated ice sheet motion. This technique is currently applied to RADARSAT data from the Antarctica mapping mission to measure ice motions\(^{1,183}\) and to analyze glacier flow dynamics.\(^{1,184}\)

So far, the atmospheric component and the image coherence are the main limitations of the interferometric method for operational DEM generation. The coherence images can also be used as SAR interferometric signatures for land use classification with ERS 1 SAR repeat-pass data.\(^{1,185}\) The interferometric correlation over forested areas was found to be significantly lower than over open canopies, small vegetation, bare soils and urban areas. The results strongly support deforestation studies, forest mapping and monitoring since it was possible not only to distinguish coniferous, deciduous and mixed forest stands, but also regrowth and clear-cut areas.

Although these results indicated that the scene coherence over forested areas was low, the interferometric technique has been used to estimate the topography and tree heights in specific conditions: a boreal forest in wintertime where the coherence varies from 0.2 to 0.5.\(^{1,186}\) The interferometric phase information used to estimate the tree height relative to an open field and compared with in situ measurements demonstrated that the scattering center at the C-band is close to the top of the trees if the forest is dense. The good coherence obtained is also a result of the stiffness of the “frozen” branches on the top of the boreal forest during the winter-time. An increased sensitivity of the degree of coherence to other environmental parameters (temperature, precipitation, snowfall and soil moisture change) was also noticed.

### 5.2 Polarimetry

SAR polarimetry has been used with success for thematic classification studies involving natural scenes and manufactured targets. A recently developed application of the SAR polarimetry involves both a direct measure of terrain azimuthal slopes and a derived estimate of the terrain elevations.\(^{1,187}\) The method is mainly based on empirical comparisons, supported by preliminary theoretical analysis, between the terrain local slope and the copolarized signature maximum shift. This has been validated over different geographical areas and different types of natural targets using different DEMs as reference. Although it was only tested with airborne P- and L-band SAR platforms, it is worth mentioning it, since future satellite missions (ENVISAT, RADARSAT-2) will generate dual-polarimetric or full polarimetric SAR data.

Polarimetric SAR measures the amplitude and phase terms of the complex scattering matrix. Based on a theoretical scattering mode\(^{1,188}\) for tilted, slightly rough dielectric surfaces, the azimuthal surface slope angles and signature-peak orientation displacements produced by such slopes are proportional over a range of azimuthal slopes. Empirical studies showed that an azimuthal angle
of a open-field terrain caused a proportional shift of the copolarized polarimetric signature maximum from its flat position by an angle almost equal to the terrain slope.\textsuperscript{187}

Since forest scattering is more complex than open-field terrain scattering, radiative transfer models or discrete scatter formulations\textsuperscript{189} of forest backscatter from a sloping terrain have to be used to modify the open-terrain algorithm. Schuler et al.\textsuperscript{187} undertook experiments with airborne polarimetric P-band SAR data (6.6 m in range by 12.1 m in azimuth with four looks) over forested terrain with slopes up to 30° in the Black Forest, Germany. They obtained low RMSEs (2–3°) and high correlation values for the measured slopes and the derived elevation profiles when compared with an accurate DEM. Attempts to use shorter wavelength radar (C- or L-bands) yielded profiles with larger errors for forested terrain, mainly for the C-band. The larger slope estimation indicates that canopy and/or branch scattering dominates over the terrain relief scattering.

The technique was later applied with L-band SAR data over non-forested areas.\textsuperscript{190} A simplified closed-form approximation to the relationship between the copolarized maximum shift and the measured covariance matrix elements is first established. Covariance matrices generated from experimental or modeling data can then be used as input parameters to derive the link with the terrain azimuthal slope. Azimuthal direction slopes can then be computed from the polarimetric SAR data without any prior knowledge of the terrain. By integrating the slope profiles in the azimuthal direction, the relative terrain elevation can be derived. To obtain the absolute elevation, one elevation point must be known along each slope profile.

To obtain 2-D topographic elevation and slope maps, sets of elevation profiles spaced throughout the range direction have to be available. Two orthogonal-pass SAR data provide a solution for generating an elevation surface with only one elevation point.\textsuperscript{190} The shape-from-shading technique, which generates slopes in the across-track direction, could also be another solution.

To apply this technique with satellite SAR data (mainly C- and X-bands), future studies should be directed towards an analysis based on volume scattering to take into account the more complicated situation of the SAR backscattering with forested or agricultural areas. With such scattering models, quantitative slope and elevation values could be derived from the relationship between radiation frequency, incidence angle and type of scattering. However, the main drawbacks of this emergent technique are the volume scattering models but also the limited availability of polarimetric data to evaluate the robustness of the technique with different topographic and land cover situations.

5.3 Altimetry

There are two kinds of altimeter: the laser and the radar. The laser scanner represents an advanced method for topographic mapping. It could replace aerial photography in a short-term period, since the laser represents an emerging technology that is making its transition from the proof-of-concept, prototype stage to a readily available and reliable commercial survey instrument.\textsuperscript{191} Automatic DEM generation over large areas is thus produced in a short delivery time. Its use is mainly restricted to airborne platforms, although a proposal was made, without success, for a satellite laser altimeter of high resolution to map the polar ice sheets.\textsuperscript{192} The instrument would have also provided useful data on cloud-top heights and the ocean surface.

The satellite radar altimeter measures the height of a reflecting facet scanned by the passage of the instrument overhead. It uses the echo delays from within the pulse-limited footprint to estimate the minimum radar range.\textsuperscript{193} Outside the pulse, a limited footprint for a flat surface is determined by the pulse length.\textsuperscript{194} As an example, the radar altimeter of GEOSAT has a pulse-limited footprint about 2 km in diameter, which increases to many kilometers as large-scale surface roughness increases. Other system limitations (inaccuracies in the timing, tropospheric and ionospheric delays of the radar wave propagation and orbit determination errors) introduce errors in the range precision, which indirectly affect the spatial resolution. However, a dual-frequency altimeter should correct for the residual ionospheric uncertainty.\textsuperscript{195} Since orbit errors are usually regarded as long-wavelength phenomena (40 000 km), least-squares adjustment using trend and bias parameters is another method to reduce errors at cross-points between ascending and descending orbit passes.\textsuperscript{196}

The two main disadvantages of conventional radar altimeters are the large footprint and its dilation with rougher terrain. A third disadvantage is that most of the radiated power falls outside the footprint and cannot be used for height estimations. Although the radar altimeter can measure distances within 10 cm, these drawbacks have reduced its applications to flat surfaces such as the ocean surface and the ice sheets. The delay/Doppler radar altimeter\textsuperscript{197} should overcome some of these difficulties:

1. More equivalent looks are accumulated to achieve a relatively small along-track footprint size (of the order of 250 m for a Ku-band altimeter). This minimizes the unwanted terrain dependence of the footprint size and position.

2. The entire along-track signal history contributes to height measurements rather than only the small pulse-limited area. It uses much more of the
instrument’s radiated energy, and thus increases the efficiency of the system.

Measuring the distance between the satellite and the ground is only the first step of a longer procedure to convert it into an elevation relative to the geoid. The geoid is the equipotential surface at mean sea level, with regard to the earth’s gravitation only. The other gravitational attractions (such as those of the sun, the moon, etc.) are classified as perturbations, which give rise to the height of the sea surface relative to the geoid.

Furthermore, the geoid is in general approximated by an ellipsoid, which deviates in height from the geoid by distances of about 50 m owing to uneven mass distribution, and the satellite orbit is determined relative to the reference ellipsoid. Therefore, both measurements (height above the sea surface and satellite orbit relative to ellipsoid) have to be obtained with the same degree of accuracy. In fact, errors in the final sea-surface height (above the geoid) calculation arises from inaccuracies in the modeling of the satellite orbit. To reduce this error the satellite should have as many ground-tracking stations as possible with globally dispersed coverage. Now the use of GPS provides sufficiently accurate means for determining the position of the altimeter satellite relative to the ellipsoid.

To resolve ocean-surface topography finally, the geoid shape relative to the reference ellipsoid should be known within a 10 cm accuracy over the ocean length scales being studied. This is not possible at this time. In fact it is the reverse. Geodesists used satellite altimetry to map the geoid over the ocean with an accuracy of about 1 m. Consequently, the best geoid estimate by geodesists is not dependent on the sea-surface height that oceanographers want to extract. For oceanographers, the time-varying aspects of ocean dynamics can thus be addressed with repeat orbits such as (i) the ocean currents or geostrophic balance (ii) ocean-circulation determination and tidal studies and (iii) ocean bathymetry.

With GEOSAT, the large number of repeat orbits (up to 64) can be processed with a third-degree polynomial to adjust the residuals between repeated altimeter profiles and a mean height profile. This averaging procedure improves the determination of the mean topography of the sea surface with an effective precision determined to be 1.5 cm. This can then be used to characterize gravity anomalies. Furthermore, short-wavelength orbit errors are also reduced. The method can also be applied on other data sources with many collinear tracks such as ERS 13- and 35-day repeat cycle data and Topex/Poseidon. The use of multiple satellite data sets yields improved track coverage and increases the feasibility of recovering the height and consequently the geopotential field in the across-track direction.

Since the 1990s, the ERS 1 and Topex/Poseidon altimeters have offered improved data quality and global data coverage in comparison with the previous altimeters from GEOS-3, Seasat and GEOSAT. In combination with its other sensors, the ERS altimeter has been contributing to scientific development in the following areas of ocean dynamic research:

- improved description of 2-D surface waves and wave heights for wave forecasting;
- ocean topography from the mesoscale to the global scale; and
- ocean-surface wind field measurement at high spatial resolution.

6 CONCLUDING REMARKS

Elevation modeling from satellite data has been a vibrant R&D topic for the last 30 years since the launch of the first civilian remote sensing satellite. Different data (space photographs, VIR scanner, SAR, altimeter) in different formats (analog, digital) can be processed by different methods (shadowing/shading, stereoscopy, interferometry, polarimetry) taking advantage of the different sensor and image characteristics (geometric, radiometric, phase) using different types of technology (analog, analytical, digital) and processing (interactive, automatic).

Most of the techniques were proposed and tested in the early years. However, the limited availability of data and associated technologies has restricted their evolution in comparison with traditional photogrammetry. Their respective evolution is also a function of the research effort in terms of physical parameter modeling and data processing.

The shadowing method, providing localized cues along special contours, is principally used to derive the relative elevation of a specific target. Despite good results, the method remains limited to specific applications. Conversely to shadowing, shading provides cues all over the studied surface, but can be applied successfully only on homogeneous surfaces. Combined with the empirical approach to resolve the different ambiguities, the method also remains marginal whatever the potential accuracy. Both methods have generated limited interest in the scientific community. On the other hand, stereoscopy is the most preferred and used method by the mapping, photogrammetry and remote sensing communities, most likely owing to the heritage of well-developed stereophotogrammetry. The latest advances in computer vision to model human vision have led to the advent of new automatic image processing approaches applied to satellite stereoscopy. Thus, the mapping
process has become more automated, but not completely with occasional unmatched expectations. Inversely, radar altimetry and polarimetry have remained more at the level of scientific interest in the physical parametric modeling without much effort made in data or image processing development.

Whether certain methods evolve depends on the trends of scientific interest. SAR stereoscopy was popular around the 1980s with the development of radargrammetry equations and the first interesting and promising results with SIR B. However, SAR image processing and related technologies to extract elevation data (such as image matching) were not mature enough and led to a temporary decline. In the same way, most of the R&D in the shape-from-shading method was done in the 1980s starting with the Venus radar mapper. At the same time, there was great interest in SPOT data with enormous research around the world in both physical parametric modeling and image processing, taking advantage also of the R&D in digital photogrammetry.

When ERS 1 was launched, scientists became enthusiastic over interferometric techniques using previously developed parametric modeling. Most research efforts were then focused in the first years on image processing (coherence image, phase unwrapping) and very few on the newly identified and poorly understood physical artefacts (atmospheric conditions, sensor calibration). With the launch of RADARSAT in 1995, there was renewed interest in radargrammetry because researchers could take advantages of the R&D in image matching realized for SPOT at the end of the 1980s, and in the new computer technologies.

It seems obvious that the R&D of the new millennium will be focused on the use of the high-resolution satellites (VIR and SAR) and the development of their associated technologies. Already some research studies have looked at the stereoscopic potential of ASTER and of the US high-resolution satellites and the interferometric potential of SRTM. Already same data acquired from these types of new satellites (ASTER, KOMSAT, IKONOS, SRTM, etc.) are used to demonstrate their real potential for topographic mapping.

Since any sensor, system or method has its own advantages and disadvantages, solutions to be developed in the future for operational DEM generation should exploit the complementarity between the different sensors, methods and processing. It has already been optimized in stereoscopy combining VIR and SAR data where the radiometric content of the VIR image is combined with the high sensitivity of SAR to the terrain relief and its “all-weather” capability to obtain the second image of the stereopair.

With the same method, some complementary aspects can be applied:

- two SAR stereoscopic pairs from ascending and descending orbit paths partially to complement the backslopes of each stereopair;
- two interferometric pairs, one with a small baseline (to help the phase unwrapping), and the other with a larger baseline (to increase the accuracy); and
- two polarimetric images from ascending and descending orbit paths to resolve the across-track ambiguity and reduce the required number of known elevation points.

The complementarity of methods has already been tried with SAR where stereoscopy is used to generate seed points needed for the clinometry or to generate an approximate DEM to help the phase unwrapping in interferometry. The loss of coherence in interferometry in forested areas can be completed with clinometry, which is well suited to the homogeneity of the forest cover. Clinometry and polarimetry could be combined since the former gives elevation information in the illumination direction and the latter in the azimuthal direction. Only one polarimetric SAR image would therefore be necessary. The shadowing method to extract building or tree heights could also be used to reduce a stereoscopic or interferometric digital surface model (DSM) in a DEM, or inversely. DSMs of cities can be used in various applications related to geographic information systems.

The complementarity can also apply at the processing level: (i) using the visual matching to seed points to the automatic matching or to postprocess and edit raw DEMs (occlusion, shadow or mismatched areas); or (ii) using stereomeasurements of geomorphological features (thalweg and crest lines, lake surfaces, etc.) to increase the mapping consistency of the DEM. Furthermore, it has been proved in most of the previous experiments that the user has to make judgements and decisions at different stages of the processing, regardless of the level of automatic processing to obtain the final DEM product: the “know-how” of the users could favorably complement the computer capability in different processing steps.

In the past, high-quality DEMs have been generated with traditional photogrammetry in such a way that they were used for many purposes. At present, DEMs are considered the most permanent and reusable geo-related data set over time. Although the need, requirements and specifications of DEM products are difficult to determine owing to their multiple uses by different user communities, a global DEM generation is realized in February 2000 with the US–German Space Radar Laboratory embarked on a US shuttle mission, the SRTM. It uses two-frequency single-pass interferometry with a second receiving antenna to generate DEMs over all land surfaces between −56° and +60° latitudes.
The accuracy of the released DEM generated by the US C-band radar interferometry should be of the order of digital terrain elevation data (DTED) level-1 accuracy. The accuracy of the DEM generated by German X-band radar interferometry will be slightly better, but with only a partial coverage of the landmass.

Is, then, a global DEM with a unique specification not a “wager”? Are these output statistics describing the global DEM helpful enough? Can we accept DEMs, which cannot produce “good-looking contour lines” in a mapping sense? Are we satisfied nowadays in producing “throwaway DEMs” at a particular scale that are maybe only good for a specific application? Will it fulfil the requirements of all DEM users? The other satellite data resellers hope not, since many new satellites with high-resolution VIR or SAR images with along- or across-track stereocapability are launched in the same time frame by US, Canadian, European, Indian, Russian, Japanese, etc., private or governmental organizations.

Global land databases present the area, spatial extent, location, and patterns of land characteristics. Land cover, the natural and artificial materials on the land surface, is the most widely available and used land data theme, but soils and elevation global databases are also found. These land data sets are key inputs to many global and regional environmental models and provide a means to parameterize key landscape processes used in studies of climate and meteorology, atmospheric chemistry, ecological dynamics, hydrology, and resource management.

1 INTRODUCTION

Global land databases present the area, spatial extent, location, and patterns of important land characteristics. While virtually any landscape theme (i.e. soils, ecosystems, terrain) can be represented in spatial databases, the most widely available and commonly used land databases in the environmental sciences involve land cover. Land cover can be defined as the natural and artificial materials on the land surface at a given point in time (e.g. cropland, forest land, wetlands, water, snow and ice, and built-up structures).

Many environmental applications require data that provide descriptions of the types of land cover or vegetation and their characteristics (i.e. canopy density and height, leaf area, albedo). Land cover affects available energy and energy partitioning between sensible and latent heat fluxes through changes in albedo, roughness, and stomatal control of water losses. The specific land cover types represented in a database correlate with the biological, thermodynamic, or chemical pathways corresponding to different vegetation associations. The types and definitions of land cover found in different global databases are variable and depend on the requirements of specific applications.

Global land databases can be either tabular or spatial. Tabular databases provide statistics of land cover area. Spatial databases are maps that provide information on the location, patterns, and extent of land cover. Spatial databases are especially important inputs to grid-based environmental models. Each grid cell has a size (e.g. 1 km², 1° latitude by 1° longitude), and an earth location that is commonly expressed in latitude and longitude or map projection coordinates.

2 GLOBAL LAND DATABASES

There is significant variability in the characteristics of global land cover databases (Table 1). In the 1980s, several coarse-resolution databases (1° latitude by 1° longitude) were produced for use in general circulation models (GCMs) and global carbon studies. The Olson and Watts database, generally referred to as the Olson Global Ecosystems map, originally consisted of 49 categories. These categories represent natural, anthropogenic or natural/modified vegetation mosaics of land cover and are optimized for use in global carbon cycle research. The Olson database has a spatial resolution of 0.5° latitude by 0.5° longitude. As such, it was the highest resolution global database of this era. It was compiled using hundreds of published maps. The accuracy of this database is unknown, as no systematic accuracy assessment has been conducted. The Olson database has undergone continual updating and improvement. The current Olson Global Ecosystems legend now consists of 94 land cover classes. However, Olson did not produce global map based on the more detailed legend.

The Matthews global database consists of two data layers. The primary layer consists of a 32-category map of potential natural vegetation and has a grid resolution of 1° latitude by 1° longitude. A secondary layer includes...
estimates for each grid cell of the percentage of cultivated land. The two layers can be combined to produce a map that approximates actual land cover. The Matthews database was developed for use in a GCM. Like the Olson map, the Matthews map was compiled from an exhaustive review of hundreds of source materials, including maps, texts, atlases, and statistical summaries. A strength of the Matthews product is that the source materials used were meticulously documented. The accuracy of this database has not been established.

A third global database is the Wilson and Henderson-Sellers global land cover database. Their database has a spatial resolution of 1° latitude by 1° longitude and contains 53 categories of land cover. Each grid cell includes a primary and secondary land cover attribute. The land cover categories include physiognomic elements, including canopy density, and have inferences to land use activities. Like the Matthews and Olson databases, the Wilson and Henderson-Sellers product was compiled from previously published materials and was designed for use in GCMs. As with the other two coarse-resolution land cover databases, the accuracy of the Wilson and Henderson-Sellers product is unknown.

Although the quality of the previously described data sets is unknown, studies suggest that improved spatial resolution and map accuracy are needed. For example, Leemans et al. made a comparison of the natural vegetation categories of the three databases (representing 75% of the global land surface). Kappa statistics were computed and used to rank similarities and differences between complex spatial patterns. The kappa results indicate only poor to fair agreement between all maps. This is also indicated by the low correspondence between all spatial patterns. Leemans et al. found that up to 60% of the cells were classified differently. This difference was most notable between Olson and Watts and Matthews. Based on the comparison, the authors concluded that these were only an approximate representation of actual land cover. Their conclusion was further strengthened by the observation that even in the tabular databases developed from country census, large differences occur between the data.

Defries and Townshend compared the Olson, Wilson and Henderson-Sellers, and Matthews classifications to determine their relative consistency. They generalized the categories from the three data sets into 15 categories, and then compared the spatial extent of each category in each data set. Their conclusions reinforced those made by Leemans et al. They found that even when the global area of a given land cover class was similar in all three data sets, the area of spatial agreement could be much smaller because the distributions were not geographically coincident. Overall, the land area where the data sets agree, for the 15 classes, was only 26% of the total surface area.

The Olson and Watts, Matthews, and Wilson and Henderson-Sellers databases were pioneering efforts. Although imperfect, they provided the first attempts to produce science-quality land databases. The differences between these global compilations of land cover exist because (1) they rely on compilation from numerous separate sources, since direct ground observations using an agreed system of classification has never been directly attempted at a global scale, and (2) widely varying criteria are used in classification.

In the mid-1990s, newer databases of higher resolution started to be developed from satellite remotely sensed data. The new data sets are based on remotely sensed data from the AVHRR on-board US National

Oceanic and Atmospheric Administration (NOAA) polar-orbiting meteorological satellites.

Defries et al. assembles a coarse-resolution land cover product from AVHRR data. This data set has 1° grid cells but was developed from a 1987 AVHRR data set averaged to 1° resolution. It was developed using supervised classification of a global 1° latitude by 1° longitude AVHRR normalized difference vegetation index data set prepared by Los et al. This data set was designed specifically for use in land atmosphere interactions modeling, and specifically the Simple Biosphere Model (SiB), and has 14 categories corresponding to SiB model requirements.

In 1997, the US Geological Survey (USGS) completed a 1-km² spatial resolution global land cover characteristics database interpreted from 1992–93 AVHRR data. The USGS database differs in that it is not based on a single land cover legend, but a database of land cover characteristics that can be interpreted on a case-by-case basis to create the data sets needed for specific applications. This database provides land cover based on seven different land cover legends commonly used for global-scale environmental research: (1) Olson Global Ecosystems for carbon cycle studies; (2) SiB for land–atmosphere interaction modeling; (3) Simple Biosphere Model Two (SiB2), and update of the original land–atmosphere interaction scheme; (4) Biosphere Atmosphere Transfer scheme, another land–atmosphere interaction model legend; (5) Running Global Land Cover, for biogeochemical modeling; (6) USGS Land Use and Land Cover, for general applications; and (7) International Geosphere Biosphere Programme (IGBP) Data and Information System Land Cover (DISCover) legend, for general environmental modeling. Figure 1 presents global land cover based on the DISCover legend. The DISCover data set is the first global land data set in which a formal accuracy assessment was completed to establish data quality. An independent accuracy assessment conducted by IGBP-affiliated researchers determined that the overall accuracy is 73.5%.

In addition to spatial databases, statistical summaries of specific land cover types are compiled by the United Nations Food and Agriculture Organization (UNFAO). UNFAO agriculture and forestry statistical databases are
based on inventory data provided by member states, or estimated using statistical sampling.\(^{(13,14)}\) In addition, the World Resources Institute (WRI) publishes annual statistical abstracts that include a variety of land cover themes.\(^{(15)}\) The WRI statistics are compiled from data collected by other organizations.

### 2.1 Land Cover Legends

It often appears that there are as many land cover legends as there are applications of land cover data. Because of the variety of land cover legends used in global studies, this discussion will be limited to the most common.

Although there are several general-purpose land cover legends, there are also many special-purpose schemes developed for specific applications. The SiB, SiB2, and Biosphere–Atmosphere Transfer Scheme (BATS) land–atmosphere interaction models are examples of single-purpose land cover legend. The classes defined for these systems represent the unique parameterization requirements of the affiliate model.

The land cover legends developed and refined by Olson and Watts (Olson Global Ecosystems) is noteworthy because it was designed specifically for global applications.\(^{(3)}\) Although not specifically developed for use with remotely sensed data, Olson has refined class definitions to permit straightforward use with satellite imagery. An added strength of Olson is that he has developed attributes describing land use, seasonality, and climate for each category. As previously stated, this legend now has 94 classes. Olson continues to add new classes and refine and improve definitions and attributes as new applications for the scheme arise.

The Matthews legend, consisting of 35 categories, is important because of its longevity. Like Olson, the Matthews database has been used in many applications. As a result, it is pervasive and accepted by many modellers. Matthews is based on the well-known United Nations Educational, Scientific, and Cultural Organization (UNESCO) vegetation classification system, and stresses potential rather than actual vegetation types.\(^{(16)}\)

The land cover classification scheme developed by Anderson et al., although not designed for global-scale studies, is important because it is one of the few designed specifically for use with remotely sensed data.\(^{(17)}\) The Anderson system is based on several important considerations. First, it is hierarchical with subsequent levels of the hierarchy defined to be mapped by increasingly larger scales of remotely sensed data. Second, Anderson classes were developed to yield consistent accuracies of at least 85% at all levels of the hierarchy. Third, the land cover classes were defined to serve as surrogates for land use. The principles from which the legend was developed have been widely accepted. As a result, it is not uncommon to see elements of the Anderson system in other legends.

The Running et al. global land cover system is an example of a legend designed both for use with remotely sensed data and for use at the global scale.\(^{(18)}\) The Running strategy is based on definitions of three canopy components: vegetation structure (termed above-ground biomass by Running), leaf longevity, and leaf type. Vegetation structure defines whether the vegetation retains perennial or annual above-ground biomass, an issue for seasonal climate and carbon-balance modeling. It is also a determinant of the surface roughness length parameter that climate models require for energy and momentum transfer equations. Leaf longevity (evergreen versus deciduous canopy) is a critical variable in carbon cycle dynamics of vegetation, and affects seasonal albedo and energy transfer characteristics of the land surface. Leaf longevity indicates whether a plant annually must completely regrow its canopy, or a portion of it, with inferred consequences to carbon partitioning, leaf litterfall dynamics, and soil carbon. Leaf type (needleleaf, broadleaf, and grass) affects gas exchange characteristics.

The IGBP developed a land cover legend for use in global change research.\(^{(19)}\) The legend consists of 17 general cover types selected based on the requirements of the IGBP Core Projects. It was designed specifically for use with 1-km remotely sensed data from the AVHRR. The categories embrace the philosophy presented by Running et al. but with modifications to (1) be compatible with classifications systems currently used for environmental modeling (e.g. SiB, and BATS), (2) provide, where possible, land-use implications, and (3) represent landscape mixtures and mosaics.\(^{(18)}\) The IGBP legend retains key elements of Running, including climate-independent class definitions and reliance on ancillary remotely sensed measures, such as vegetation greenness indices, as relative indicators of temporal dynamics of biophysical properties.

### 2.2 Other Global Land Data

Global environmental studies also require data on other themes including spatial databases on soil types and characteristics and elevation. Digital elevation model (DEM) data provide estimates of the average elevation within grid cells. DEM data can be used to derive important terrain characteristics such as slope, aspect, hydrologic basins, and stream networks. The USGS, for example, distributes a 1-km\(^2\) resolution global DEM.\(^{(20)}\) A 1° latitude by 1° longitude resolution global soils database has been produced from the UNFAO Soils Map of the World.\(^{(21)}\) This data set has 1° latitude/longitude

3 EXAMPLES OF GLOBAL LAND DATA APPLICATIONS

Global land data sets are used in a wide range of applications, including climate modeling, biogeochemical cycle analyses, ecosystem dynamics, carbon cycle studies, hydrological processes, and resource management. The specific data requirements vary according to the geographic extent, spatial resolution, and thematic attribute requirements of each study. It is important to note that the applications of land cover data vary both within and between disciplines and applications (Table 3). The following sections provide brief summaries of selected applications of global land cover data.

Global environmental applications have two basic components. First, numerical models accounting for interactions and feedbacks between different earth systems are needed. Second, a large amount of geographically referenced, validated data will be needed to parameterize these models adequately. Land cover data are used to partition the landscape into geographic units corresponding to a broad suite of environmental parameters, such as surface roughness, albedo, latent and sensible heat flux, and associated biogeochemical processes and cycles. Changes in the distribution of land cover alter the regional and possibly global balance of these fluxes. Changes in land cover distribution include both the often-cited conversions of one land cover type to another (e.g. forest to cropland, grassland to urban), and also the seasonal changes in land cover parameters. The seasonal development of foliage,

for example, over a period of less than a few weeks can affect local weather.\(^{(22)}\)

### 3.1 Climate and Meteorology

Land cover data are increasingly important in GCMs used to simulate global climate and in mesoscale meteorological models that provide regional weather forecasts. Several land surface parameterization models have been developed for the purpose of estimating suites of parameters that affect the interaction between land cover and the atmosphere.\(^{(22)}\) Land cover databases provide boundary conditions from which surface fluxes of energy, moisture, and momentum are estimated. The SiB model by Sellers et al.\(^{(23)}\) and the BATS model by Dickinson et al.\(^{(24)}\) were among the earliest land surface parameterization models to use land cover data to realistically represent landscape processes in atmospheric models.

There is considerable experimental evidence that modeled atmospheres are sensitive to landscape characteristics, and that changes in water availability at the earth’s surface, or changes in albedo, produce large changes in the numerically simulated climates.\(^{(25)}\) Numerical experiments using global circulation models have demonstrated that landscape characteristics affect not only the regional atmosphere, but also modify global climate. Land cover parameters important in affecting mesoscale circulation include leaf area index as a function of height, stomatal resistance, albedo, aerodynamic roughness, displacement height, percentage coverage, and photometric properties. Pielke and Avisar conclude that global data sets need higher spatial resolution than the 1980s 1° cells so that GCMs can provide information on local circulation.\(^{(25)}\)

The impact of land cover on climate is illustrated in the Copeland et al. study comparing the United States climate generated using both current and presettlement land cover conditions.\(^{(26)}\) In this simulation study, they found that differences in vegetation parameters, resulting from the change of land cover from natural to modified conditions, affected most climate variables. For example, they found that changes in roughness length, leaf area index, and albedo changed significantly when natural vegetation was replaced by anthropogenic land uses. Overall, Copeland et al. found that the mean daily temperature increased by 0.05 K because of land cover change.\(^{(26)}\) Locally, temperature changes were in excess of 1–2 K warmer or cooler, though warming dominated. The temperature changes were the result of a change in the surface energy balance. Albedo changes led to changes in net radiation available at the surface, but changes in the partitioning of that between latent and sensible heat flux due to leaf area index and fractional coverage changes determined whether a region heated or cooled. Precipitation rates generally increased throughout the USA, by about 5% (0.09 mm day\(^{-1}\)). Local changes in precipitation rates were typically 5–10% above historical land cover scenarios. Changes tended to occur along the ecotones, or boundaries between vegetation types. The overall result of this modeling suggests that current land cover has caused summertime surface conditions to be warmer and wetter than natural landscapes would indicate.

Modeling exercises using global land databases continue to probe the sensitivity of climate system to surface processes. These efforts can only be successful if global-scale data sets are available for initialization and validation.

### 3.2 Atmospheric Chemistry

Investigations of atmospheric chemistry use land cover to estimate the amount and mixing of biogenic emissions in the atmosphere. Emission inventories of biogenic volatile organic compounds (BVOC), such as isoprenes and monoterpenes from vegetation, are important inputs to models that simulate photochemical smog.\(^{(27)}\) The impacts of BVOC can be important in understanding ambient air quality, since BVOC emissions from vegetation can be greater than those from anthropogenic sources. BVOC emission potentials for different land cover types vary by more than three orders of magnitude.\(^{(28)}\)

The chemistry of the atmosphere is strongly influenced by ecological processes that control the emission of water and trace gases from plants. Vegetation-based emissions of BVOC could have a significant impact on tropospheric chemistry by influencing the processes that control the formation of atmospheric haze. Isoprene and monoterpenes are typically regarded as the predominant BVOC emitted by plants. The land cover elements that control natural BVOC emissions are (1) landscape average emission potential, (2) foliar density, and (3) emission fluxes that are based on interaction with light and temperature conditions.\(^{(28)}\) The accuracy of regional BVOC emission models is limited by a lack of emission rate measurements and appropriate land cover databases. Most regional emission models classify landscapes into three or four woodland categories and several nonwoodland landscapes. A significant improvement should be expected if landscapes are classified according to species composition.

### 3.3 Ecological Applications

Biogeochemical models address a variety of ecological processes and have contributed to significant advances in the understanding of the global cycles responsible for the compositions of the atmosphere, oceans, and sediments on the surface of the earth.\(^{(29)}\) Land cover attributes describing community composition or vegetation types
are used in biogeochemical models (e.g. CENTURY by Parton et al.\textsuperscript{30} and BIOME-BGC by Hunt et al.\textsuperscript{31}) to parameterize assimilation rates, carbon allocation, and nutrient use efficiency, which influence CO\textsubscript{2} uptake during photosynthesis.\textsuperscript{22}

There are numerous studies illustrating the use of global land databases for ecological assessments. For example, Burke et al.\textsuperscript{32} highlight the importance of land cover in simulating the temporal dynamics of soil organic matter and plant production in grazed grasslands and agroecosystems using the CENTURY model. Land cover, along with other important driving variables including surface-soil physical properties, monthly precipitation and temperature, and plant nitrogen and lignin contents were inputs to an assessment of the impacts of a CO\textsubscript{2} doubling scenario on soil carbon. Burke et al.\textsuperscript{32} found that 35–50\% of soil organic matter in the Great Plains was lost as a result of 50 years of cultivation in the region. The simulation suggested that all croplands had significant losses of soil organic matter but that rangelands did not. Intermediate losses occurred in irrigated corn because of the relatively high tillage intensity, and lowest simulated losses occurred in continuous wheat and dryland corn. Across all cultivated areas, an average of 44\% of soil organic matter in the top 20 cm was lost; across the entire region (i.e. all land use types), 21.5\% of surface carbon was estimated to be lost over 50 years.

One of the most modeled ecological parameters, global net primary productivity (NPP), is complicated because the models used differ markedly in approach, complexity, and land cover inputs.\textsuperscript{33} NPP models use a wide range of spatial data, including vegetation species, climate, soils, plant characteristics, disturbance regimes, and a number of other natural and anthropogenic factors. Past global databases lacked the land cover attributes needed for NPP modeling. Estimation of NPP is complicated by the fact that the plant characteristics that affect this parameter vary both within and among species. Improvements in global data are a critical foundation for accurate NPP estimates for a wide array of global change scenarios.

Global data sets have also been used to assess large-area patterns of environmental diversity.\textsuperscript{34} Land cover data can be used to approximate large-area biodiversity patterns. Land cover serves as a surrogate for habitat and can thus be used to identify potential distributions of flora and fauna. In a study of US land cover, Wickham et al.\textsuperscript{34} observed that the general pattern of increasing diversity from east to west is in contrast with latitudinal gradients in species diversity at continental global scales. This north–south terrestrial species gradient appears to result from a similar gradient in available energy.

A general conclusion regarding global land cover data for ecological applications is that the ecological community stressed the need to develop land data sets of the highest possible resolution.\textsuperscript{35} For ecological assessments, grid cell sizes may sometimes need to be aggregated, but more frequently fine resolution is essential for ecological models.

### 3.4 Hydrological Modeling

Modeling in hydrology appears to have lagged behind atmospheric and ecological processes modeling.\textsuperscript{36} Hydrological modeling requires land cover data for modeling the physical processes of the hydrological cycle. However, land cover is typically treated as uniform through a watershed. Vegetation interacts with the atmosphere by its controls on the return of water back to the atmosphere, as evaporation and transpiration. Therefore, land cover has a significant impact on the hydrological cycle and consequently on other components of the climatic system. Land cover influences the exchange of energy, water, carbon, and other substances at the land–surface–atmosphere interface. Its form affects the absorption of solar radiation. Plant leaves and branches increase the surface area for evaporation, intercept part of precipitation, and by increasing friction for air movement increase the thickness of the boundary layer. The IGBP biological aspects of the hydrologic cycle (BAHC) core project aims to serve as a catalyst for the improvement of future hydrological models. BAHC plans stress the need explicitly to assess and represent the relevant topographic, vegetation, soil, and geological parameters that control soil moisture and surface and subsurface hydrological conditions in order to improve the results of hydrological simulations.\textsuperscript{37}

### 3.5 Resource Management

There are many regional applications of large-area land cover databases in activities associated with resource management. For example, US Department of Agriculture policy makers used land cover data to assess drought and flood conditions for crop land areas.\textsuperscript{38} Land cover data provided a means to focus flood and drought analysis on key agricultural areas in the midwestern USA.

In a unique application, the US Air Force uses coarse-resolution land cover to model the potential for bird collisions with low-flying aircraft.\textsuperscript{39} The Air Force uses a bird avoidance model to provide localized data on bird distributions and abundance throughout the continental USA.
4 FUTURE GLOBAL LAND DATA DIRECTIONS

Perhaps the clearest direction in global land data set characteristics is the movement toward higher resolution (i.e., 1 km). Although there are currently no global environmental modeling applications using 1-km data, or for that matter resolutions higher than 50 km², there are a number of significant reasons why a 1-km global land cover database is important for global environmental studies. These include:

- The 1-km global land cover database will have improved historical relevance since it can serve as a time-specific baseline of regional to global land cover patterns and areal extents.
- A wider range of applications can be met with a higher resolution land cover data set. As illustrated in Table 3, the grid cell dimensions vary both within and between types of environmental modeling applications. A 1-km global land cover database has the spatial resolution that meets the minimum spatial resolution requirements of all current large-area environmental models.
- A variety of fundamental research opportunities are possible, particularly those dealing with scaling and landscape heterogeneity issues.
- Regional modeling can be conducted at higher resolutions. For example, mesoscale meteorological models are now being run at resolutions from 1- to 40-km grid cells.
- Flexible sub-grid cell parameterization requires incorporation or analysis of landscape heterogeneity. Higher resolution data provides a means either to apply flexible aggregation strategies to represent the internal heterogeneity of grid cells, or an ability to incorporate higher resolution parameterization models to calculate grid cell biophysical parameters. Thus, 1-km data can be aggregated to other grid dimensions (e.g., 10-, 20-, 50-, 100-km, etc.) using intelligent methods for determining the landscape types most important to the problem being addressed.
- Coupled models can be run with differing resolution land cover inputs, but still based on consistent land cover data. For example, a GCM with a 4° latitude by 5° longitude horizontal grid can be used to estimate future climate trends. The climate results of the GCM can be input to a mesoscale meteorological model operating at a 40-km² resolution to simulate regional hydrological variables. This can then be input to agriculture production models operating at a 1-km resolution. The 1-km source data from the global land cover database can be aggregated to the grid cell resolutions used by all models, allowing use of a single, consistent land cover source.

Several additional trends will likely affect future global land cover databases. One challenge is the need for increasingly more complex descriptions and attributes describing land cover and associated characteristics. A key problem is associated with the fact that land cover data have traditionally been represented using discrete scales of measurement. However, mathematical models typically use continuous data. As a result, thematic data, such as the categories used with traditional land cover and soils maps, must be converted to parameter values (e.g., stomatal resistance, surface roughness, leaf area index) which can be used in numerical calculations. An example of this is the effort to quantify forest canopy characteristics such as percentage canopy cover and percentage leaf type. The trend toward continuous variables means that researchers must use measurements from limited field or laboratory studies and judgment to select the values that are associated with particular land cover classes, and modify and retest models based on the new types of inputs.

A related challenge is that environmental processes operate on many different time and space scales, and there may be scale thresholds at which critical processes change. To accommodate increasingly dynamic models, data sets will need to be multiscale and multitemporal, while still being consistent over large areas.

New global land data sets will have accuracy assessments that quantify data quality levels. This trend will provide the science quality data needed for new generations of earth systems models. While the recent IGBP DISCover database has documented accuracy, there is still considerable work needed to develop sound, yet practical, validation standards.

Finally, a new generation of satellite sensors will become operational in the early years of the twenty-first century that will provide imagery that are particularly well suited for developing global land data. The French satellite Système Probatoire pour l’Observation de la Terre (SPOT) vegetation sensor and the US Earth Observing System Moderate Resolution Imaging Spectrometer (MODIS), for example, will provide global data with appropriate resolution and spectral characteristics for generating a wide range of new land data sets. There are already plans to establish specialized, operational quantitative databases using MODIS data. MODIS processing plans call for the routine development of global data sets on albedo, land temperature, burned areas, land cover, and land cover change.

Environmental models are rapidly increasing in sophistication owing to (1) improvements in computing hardware performance, (2) increasing use of geographic
information systems and object-oriented databases, and (3) scientific advancements in earth systems science. Data inputs to these models must be based not only on today’s immediate needs, but also the anticipated requirements of the next generations of models. A 1-km global land cover database should meet the needs of the majority of the modeling community for the next several years.

Hyperspectral imaging (HSI) spectrometers are remote sensing instruments that acquire images in a large number, typically hundreds, of contiguous spectral channels throughout the visible to long-wave infrared (IR) portions of the spectrum from 0.4 to 14 µm. These systems are usually flown on aircraft platforms and use either platform motion or mirror mechanisms to scan a region of the earth’s surface. The high-resolution spectral features represented in the data cube allow for discrimination of materials in a scene. Because of the large number of spectral channels that are acquired by these instruments, they are termed hyperspectral, in contrast to multispectral instruments that obtain relatively few spectral bands. Like all remote sensing technologies, HSI must contend with data perturbations caused by atmospheric effects. In addition, data analysis must account for spectral mixing of multiple constituent materials within each pixel’s field of view (FOV).

1 INTRODUCTION

1.1 Hyperspectral Imaging

HSI is a form of spectroscopy, the study of how electromagnetic radiation is reflected, scattered, absorbed by, or emitted from the surface of a material. Hyperspectral sensors typically operate throughout the visible to long-wave IR portions of the spectrum from 0.4 to 14 µm (Figure 1) and measure an effectively continuous spectrum for each pixel in a scene, generating an image data cube with two spatial dimensions and one spectral (Figures 2 and 3). Solids, liquids, and gases interact with photons differently at different wavelengths. The wavelength dependence of absorption processes is used to derive information about the chemistry of a material and to identify a material from its spectral signature. For example, some of the major spectral absorption features in vegetation can be attributed to plant pigments, such as chlorophylls, which produce a highly characteristic vegetation reflectance signature (Figure 4).

Hyperspectral systems can be contrasted with traditional multispectral systems (see section 4.1) which produce radiance measurements corresponding to an integrated response over broad spectral channels. A typical multispectral instrument obtains one measurement over a wide spectral band whereas the hyperspectral system obtains approximately 100 measurements covering the same spectral region (see Figure 5). Multispectral systems differentiate amongst general classes of materials, while hyperspectral instruments support detailed identification and quantification of materials.

Hyperspectral remote sensing combines the analytical power of spectroscopy with the established data collection and processing techniques of remote sensing but encounters new challenges. For example, chemical analysis via spectroscopy has not typically been complicated by data corruption due to inhomogeneous scene illumination and atmospheric absorption and scattering. The analysis is further complicated if pixel-to-pixel quantitative comparisons of surface features are desired and there exist substantial illumination and water vapor variations over the FOV. Analysis algorithms robust to these spatial inhomogeneities are required.
1.2 Information Resources

Hyperspectral remote sensing is a young field; not many texts are available that specifically deal with its capabilities and challenges. In regard to multispectral remote sensing, which shares many challenges with HSI, Muller provides a good introduction and historical perspective. Landgrebe gives an excellent discussion of multispectral and hyperspectral data analysis and information extraction. Good general overviews of spectral reflectance signatures and remote sensing technology and analysis are available. Wolfe has provided a most useful work on the physics of imaging spectrometers. Various government agencies and research institutes have published technical reviews and reports. Proceedings from the AVIRIS (airborne visible/infrared imaging spectrometer) workshop, which has been held by the Jet Propulsion Laboratory (JPL) since 1989, provide an excellent source of papers on HSI applications.

Numerous articles on hyperspectral applications and analysis techniques have appeared in remote sensing journals such as the IEEE Transactions on Geoscience.
and Remote Sensing, Remote Sensing of Environment, International Journal of Remote Sensing, and Photogrammetric Engineering and Remote Sensing. Over the last several years, most remote sensing and optical instrumentation conferences have held sessions devoted to HSI and its applications. These conferences include Applied Geologic Remote Sensing, Remote Sensing for Marine and Coastal Environments, International Airborne Remote Sensing Conference, the Annual SPIE Meeting (Optical Science, Engineering, and Instrumentation): Imaging Spectrometry Conference and others. The proceedings from these meetings are an important resource of information on HSI.

2 SPECTROSCOPIC CONSIDERATIONS

2.1 Interaction of Light with the Atmosphere
When radiant energy is incident on a material's surface, a portion of that energy will be reflected, absorbed,
or transmitted at various wavelengths. From these surface interactions one can infer the characteristics of the material being observed. However, all radiation recorded by a remote hyperspectral imager passes through some distance, or path length, of atmosphere. Each time radiant energy passes through the atmosphere, it undergoes absorption and scattering, significantly altering the intensity and spectral composition of the light that is available for detection by the spectrometer. Therefore, the atmosphere is a primary determinant of the operational range of the instrument.

Atmospheric absorption processes convert incoming radiation to heat through an exchange of energy between a molecule and the incident electromagnetic energy. The most efficient absorbers of solar radiation are water vapor, carbon dioxide, ozone, and oxygen. These atmospheric constituents attenuate radiation very strongly in certain wavelength bands and it is the wavelength ranges outside these main absorption bands that are used for HSI. The wavelength regions that are useful for imaging are known as atmospheric transmission windows (see Figure 6). Although the earth cannot be observed in regions of high atmospheric absorption, these wavelength ranges can be used for atmospheric sounding and are the basis of current atmospheric retrieval and correction algorithms (see section 5.2).

In the atmospheric transmission windows, scattering by atmospheric particles is the dominant mechanism affecting the spectrometer’s ability to correctly measure surface radiance. Scattering removes energy from the incident electromagnetic wave and re-emits some portion of it at the same wavelength but in different directions. When atmospheric particles are much smaller than the wavelength of incoming radiation, Rayleigh scattering is the dominant scattering mechanism. Rayleigh scattering is proportional to \(1/\lambda^4\), where \(\lambda\) is the wavelength of incoming radiation; therefore, this mechanism preferentially attenuates shorter wavelengths. Rayleigh scattering accounts for the blue color of the sky. Since the shorter wavelengths (blue to ultraviolet regions of the spectrum) are scattered more strongly than the longer (red) wavelengths, an observer will see blue light when looking at the sky in any direction.

When the sizes of the atmospheric particles are approximately equal to the wavelength of the incoming radiation, Mie scattering occurs. This mechanism is wavelength dependent but influences longer wavelengths than Rayleigh scattering. Generally, atmospheric Mie scattering becomes significant when dust, haze, fog or smoke are present.

Nonselective scatter, where radiation is scattered equally in all directions, occurs when the atmospheric particles are much larger than the wavelength of the incoming radiation. For example, water droplets with diameters on the order of 5 to 10 \(\mu\)m cause nonselective scattering. In the visible wavelengths, thick clouds or fog appear white or bluish-white due to isotropic scattering by these larger particles.

### 2.2 Spectral Properties of Selected Materials

In the visible/near-infrared (VNIR, 0.4–1.1 \(\mu\)m) to short-wave infrared (SWIR, 1.1–2.5 \(\mu\)m) wavelength range, hyperspectral instruments measure reflected solar radiation after it passes through some path length of atmosphere. The shapes of reflected spectra depend on the atmosphere and on a variety of surface properties (e.g. pigmentation, moisture content and leaf morphology, mineral and moisture contents of soils, and level of sedimentation in water). Figure 7 shows hyperspectral images with corresponding spectral radiance curves (in the 0.4 \(\mu\)m to 2.5 \(\mu\)m range) for a variety of land cover types. Some of the characteristic features of these materials are visible in the spectral curves.

The major absorption features in vegetation spectra can be attributed to plant pigments (chlorophylls, xanthophyll, and carotenoids) and water. The dip in the spectrum at 0.65 \(\mu\)m is caused by the strong absorption of incoming radiation by chlorophyll a and b in the leaves. The other two dips at 1.45 to 1.55 \(\mu\)m and 1.90 to 1.95 \(\mu\)m are caused by water absorption in the leaves. The absorption features seen in vegetation spectra are related to organic compounds common to the majority of plant species. Other minor features are attributable to components including cellulose, lignin, proteins, starches, and sugars (see Table 1). In the 0.7 to 1.0 \(\mu\)m range, leaves are highly reflective due to the cellular structure of leaf tissue. In this wavelength range, vegetation spectra typically exhibit a strong plateau, the height of which decreases as moisture stress increases.

Bodies of water have a low spectral reflectance (less than 10%) in the visible, blue-green region. At wavelengths longer than 0.75 \(\mu\)m, water absorbs almost all incoming solar radiation. Therefore, most applications of
Figure 7 Hyperspectral imagery of different ground cover types, acquired by the TRWIS (TRW Imaging Spectrometer) III instrument. Each pixel of the image corresponds to a 384-band spectral measurement of a ground sample. The gap in the spectral curves (starting at band number 128) corresponds to the overlap region between the SWIR and VNIR spectrometers. The images have been calibrated to radiance units of 0.01 W (m² sr µm)⁻¹.

HSI to water environments use the wavelength range of approximately 0.4 to 0.6 µm, where valuable information about water condition can be gleaned (see section 3). In this range, however, Rayleigh and aerosol scattering contribute strongly to the reflected energy measured by a hyperspectral sensor, and an accurate estimate of this atmospheric contribution is necessary. Water reflectance can also change dramatically as a result of the presence of suspended organic or inorganic materials, and shallow, clear water bodies can exhibit an increased reflectance due to reflections from bottom materials. Taken together, all of these phenomena make applications of remote sensing to water particularly difficult.

HSI reveals a wealth of information about minerals, and geology is perhaps the most mature application of imaging spectrometry to earth observation. Solar radiation induces electronic transitions, charge transfers, and molecular vibrations, which generate a variety of distinctive spectral features useful for mineral identification. In the 0.4 to 2.5 µm range, wavelength dependent absorption bands in mineral spectra are due to electronic transitions. For example, water and hydroxyl produce particularly characteristic absorption features at approximately 1.4, 1.9, 2.2, and 2.7 µm. The strong hydroxyl features have proven to be particularly diagnostic of clay mineralogy. Carbonates produce a number of absorption features at 1.9, 2.0, 2.16, 2.35, and 2.55 µm.

In the long-wave infrared region (LWIR, 8–14 µm), rather than measure reflected solar radiation, hyperspectral instruments detect the energy being emitted from the earth’s surface or from objects on the ground. In the thermal region a material’s emissivity is the property of interest, where emissivity is a wavelength dependent measure of a material’s ability to emit energy in comparison to a blackbody. Real objects are not perfect radiators and emit only a fraction of the energy of a blackbody at the same temperature. Spectral features of minerals in the LWIR are due to molecular vibrations, and similarly in the VNIR/SWIR range, distinctive features in the emissivity spectrum can be used for mineral identification.
For example, reststrahlen bands are characteristic features of silicate minerals in the wavelength range beyond 8 µm. The reststrahlen features are emissivity minima that move from shorter to longer wavelengths as silicate content decreases. In general, signatures of materials tend to be flatter and exhibit less peak-to-valley spectral variation in the LWIR than in the reflected VNIR/SWIR ranges.

3 APPLICATIONS OVERVIEW

Because HSI yields an abundance of information about materials covering the earth’s surface, a wide range of problems can be addressed using this technology. This section will briefly describe some of these applications. More details can be found in the references and in the other sources mentioned in section 1.2.

As previously noted, geology and mineralogy are perhaps the most mature applications of HSI. Multispectral imagery has long been applied to geologic exploration. Imagery from the Landsat Thematic Mapper and Multispectral Scanner has been used to distinguish rock types, create mineral maps, and delineate major folds and fracture systems. However, the spectral resolution of Landsat and other multispectral scanners is not sufficient to uniquely determine the mineralogic composition of rocks. For example, a feature at 2.2 µm can be caused by sericite or kaolinite. With measurements of sufficient spectral resolution the minerals can be differentiated. An absorption feature due to pyrophyllite is centered at 2.17 µm. The feature is broadened when other hydroxyl-bearing minerals are present. For a multispectral system, the broadened feature is indistinguishable from the characteristic spectrum of alunite, and only measurements of sufficiently high spectral resolution can detect that alunite is not present. Figure 8 shows an example where high spectral resolution in particular wavelength bands is necessary to differentiate between minerals.

HSI allows not only mineralogic identification and classification but also quantitative estimates of surface mineral abundance. Early work with the airborne AVIRIS sensor (see section 4.2) demonstrated that hyperspectral data could be used to derive both detailed mineral maps of large areas and mineral abundance estimates at the individual pixel level. These remotely derived image products were verified through ground studies of the surveyed areas. In recent years, as the signal-to-noise performance of detectors has improved and processing algorithms have been refined, even finer spectral features have been measured, leading to extremely detailed mineral maps and accurate abundance estimates at the sub-pixel level. The region of Cuprite, Nevada has been used as testing ground for new scanners and mineral classification algorithms. Over a number of years, this area has been characterized by ground, airborne, and satellite measurements, and the detailed maps that have been generated from hyperspectral data are an indication of the advancements in mineralogic identification that are possible with HSI.

Hyperspectral sensors have been used for oceanographic studies and to image bodies of water, including oceans, coastal regions, inland lakes and rivers. The high spectral resolution of these instruments has contributed to the understanding of complex water environments, such as coastal regions, where suspended sediments, bottom reflectance, and dissolved organic matter make the interpretation of optical remote sensing data particularly difficult. In water bodies where there is sufficient penetration of solar energy, bathymetry (depth measurement) has been performed. Hyperspectral image data have been used to address an important component of marine remote sensing: the detection of phytoplankton to derive estimates of biological activity. In certain water bodies, multispectral sensors have been used to detect pigments, such as chlorophyll, a photosynthetic pigment common to all algal groups. However, hyperspectral sensors allow measurement of specific absorption features that are unique to pigments other than chlorophyll. The detection of these pigments is applicable to the understanding and characterization of algal blooms, which can be harmful to humans and the ecosystems of bays and rivers.

Another major application area for hyperspectral remote sensing is the observation of vegetation. Traditionally, remote sensing techniques, from aerial photography to multispectral imaging, have been used to...
map the area and extent of vegetative regions. But HSI has been used to produce accurate maps of vegetation varieties for a wide range of landscapes, from national parks to agricultural fields. This technology also generates a wealth of information about the biophysical and biochemical attributes of a living and changing vegetation ecosystem. Several studies have investigated the relationship between remotely sensed hyperspectral data and the foliar chemistry of forests, grasslands, and wetland canopies. These data have been used to generate maps of foliar nitrogen, which is strongly related to the rate of photosynthesis and can be used to predict forest growth rates. Hyperspectral data have also been used to produce estimates of canopy water content, which are applied to risk assessment and mitigation for fire-prone regions of urbanized landscapes. The ability to measure the spectral changes in vegetation during its growth cycle also has implications for forestry and agriculture, particularly in the area of precision farming. HSI can be used to perform crop and forest inventories, crop health assessments and pre-visual stress detection without extensive field work.

Along with remote sensing of the earth’s environment, HSI has demonstrated utility in the area of target discrimination and identification. Because man-made materials can be accurately identified, and even quantified, by remote measurement of their distinct spectral signatures, hyperspectral data are used to accomplish a number of target detection missions. These applications include distinguishing vehicles, target panels, and fabrics in a variety of natural and urban backgrounds, anomaly detection, classifying target signatures in real time, and detecting subpixel-sized targets. HSI is also relevant to the problem of detecting buried land mines. Many well-known hyperspectral image analysis techniques (see section 6) are directly applicable to this type of data, but a primary concern of data exploitation in this regime is to minimize the false alarm rate of the detection process. By reducing the number of incorrectly identified targets, hyperspectral image analysis becomes well suited to the problem of real-time target detection.

4 DATA COLLECTION

A number of approaches are available for multispectral imaging and HSI, but most fall in three categories: those using bandpass optical filters, dispersive elements (prisms or diffraction gratings), and interferometers. Devices based on optical filters provide the easiest technical solution for multispectral imaging and were the basis of the first multispectral sensors. However, these suffer from a practical limitation in the number of spectral bands they can monitor. In the early 1980s the fabrication of large focal plane arrays facilitated the development of dispersive and interferometric hyperspectral imagers capable of simultaneously measuring hundreds of spectral bands.

Dispersive HSI sensors (see section 4.3), take instantaneous spatial/spectral frames, concatenating many frames over time to furnish the second spatial dimension of a data cube. On the other hand, an imaging Fourier transform spectrometer (IFTS, see section 4.4), takes instantaneous two-dimensional spatial frames of spectral interference amplitudes, concatenating many frames and applying a fast Fourier transform (FFT), to produce the spectral dimension of a data cube.

4.1 Early Instruments

The first multispectral scanner was developed by the Environmental Research Institute of Michigan in 1963 as an airborne instrument. The age of orbital multispectral imagery began in 1972 with the launch of Landsat-1. These and other early instruments typically employed 6 to 16 spectral filters to select wavelength bands that facilitate the characterization of terrain features. The development of two-dimensional focal plane arrays made HSI possible. An IFTS was first described in 1972 by Potter, who also helped produce a simple instrument in 1980. The first deployed HSI, the Airborne Imaging Spectrometer (AIS), was built by NASA (National Aeronautics and Space Administration) JPL in 1983, and used a 64 × 64 element focal plane. AIS was a near-IR and SWIR imager that employed dispersive optics. The development of true IFTs was delayed until the early 1990s, pending the availability of high speed microcomputer boards capable of rapid FFTs.

4.2 Contemporary Instruments

The number of multispectral and hyperspectral instruments has grown steadily in the 1980s and 1990s. At the time of writing, orbital collection remains the domain of multispectral imagers like Landsat and SPOT (Système Pour l’Observation de la Terre), but this situation will change soon with the launch of NASA’s EO-1 satellite that carries the Hyperion HSI sensor. A variety of airborne hyperspectral imagers (AHIs) are in service. Some are IFTs (e.g. SMIFTS (Spatially Modulated Imaging Fourier Transform Spectrometer), LIFTIRS (Livermore Imaging Fourier Transform Infrared Spectrometer), HRIS (High-resolution Imaging Spectrometer)), but most use dispersive optics (e.g. AVIRIS, HYDICE (Hyperspectral Digital Imagery Collection Experiment), TRWIS III, SEBASS (Spatially Enhanced Broadband Array Spectrograph System), AHI). The latter group use slit camera designs that capture
images by scanning scenes. Some are “pushbroom” scanners (e.g. TRWIS III), that is, the scan motion is provided by the platform’s movement and is in the direction of flight. Others are “whiskbroom” scanners (e.g. AVIRIS), that sweep the imaging slit back and forth perpendicular to the direction of flight.

Beside construction differences, hyperspectral imagers can be grouped according to spectral domain. Fourier transform spectrometers are capable of resolving finely separated spectral lines and have proven most useful in the medium-wave infrared (MWIR, 3–5.5 µm) and LWIR regimes where we observe the vibrational and rotational structures of gas absorption and emission.\(^1\) Dispersion-based instruments tend to perform better for broader spectral features, such as those found at VNIR and SWIR wavelengths. Dispersive instruments are also useful in the MWIR and LWIR regimes when high spectral resolution is not needed, but precise radiometric calibration is required.

Whereas multispectral devices often cover bands throughout the visible and IR spectrum (e.g. AHS, DAIS, MVIS), present hyperspectral sensors tend to concentrate on one or two ranges, such as VNIR (e.g. CHRISS (Compact High-resolution Imaging Spectrographic System), TRWIS B), VNIR/SWIR (e.g. HYDICE, AVIRIS, TRWIS III), SWIR/MWIR (e.g. SMIFTS), or MWIR/LWIR (e.g. LIFTIRS, AHI).\(^{1,32,36,37}\) Focal plane materials and operating temperatures vary markedly for these spectral regimes. Ambient temperature silicon charge-coupled device (CCD) arrays, like those used in video cameras, work well for VNIR sensors. In the SWIR regime, cooled InSb or HgCdTe photodiode arrays are frequently used; HgCdTe, PtSi and Si:In arrays have been used in the MWIR; HgCdTe, Si:As and Si:Ga in the LWIR.\(^1\) Materials used for MWIR and LWIR detectors require extreme, stable cooling to function reliably. LWIR devices have a further complication: uncooled collection optics emit radiation at LWIR wavelengths and this contributes background signal at the focal plane.

In the next two sections we present detailed descriptions of dispersive and Fourier transform HSI devices.

### 4.3 TRW Imaging Spectrometer III: A Dispersive Hyperspectral Imager

The TRWIS III, shown in Figure 9, is a dual hyperspectral imager. A VNIR instrument covers the 0.4 to 1.0 µm spectral regime, and a co-aligned SWIR imager covers 0.9 to 2.5 µm.\(^{38}\) Table 2 summarizes the instrument parameters. The TRWIS III measures a 13.1 degree swath in 384 spectral bands with 256 pixels of spatial resolution. It is a slit camera, meaning its optical FOV must scan over a scene to render an image. Typical TRWIS III images comprise 1500 lines and are rendered in about 30 s. The information content of one hyperspectral image is huge: a 384 × 256 × 1500 pixel data cube comprises nearly 300 Mbytes (12 bit precision, stored as 16 bit integers).

Figure 10 offers a simplified diagram illustrating the basic operation of a grating-based HSI like TRWIS III. Foreoptics focus the input scene on a narrow slit. A bandpass filter limits the wavelength range of accepted light. The image component passing through the slit is collimated and directed to a diffraction grating. Here the spectral components of the image are dispersed at different angles such that the axis of dispersion is perpendicular to the slit. Light diffracted off the grating is focused on the VNIR or SWIR focal plane. The VNIR device uses a silicon CCD array and the SWIR instrument uses a HgCdTe photodiode array maintained at 115 K by a cryogenic cooler.

15 and 240 Hz and determines how quickly the camera slit can be scanned over the scene to produce square spatial pixels. Scanning faster than this critical rate does not overlook data, but stretches the pixel footprint – the ground sample distance (GSD) – along the scan direction. Scanning slower over-samples the scene spatially along the scan direction. Even at the critical scan rate, where the pixel footprint is square, there are some data mixing along the spatial scan direction because light is collected continuously at the focal plane. Approximately 25% of the signal in a pixel comes from landscape immediately before and after the current ground sample area (see Figure 11).

Samples of TRWIS III data cubes are shown in Figure 7. These images are partial representations of the full data cube – three spectral bands corresponding to typical red, green and blue wavelengths are merged to form a composite color picture. The spectral profiles of some representative spatial pixels are shown. An alternative presentation of HSI data involves combining bands in specific ratios to extract hidden details or highlight differences between spectral profiles. Samples of this exploitation technique and the

Figure 10 Schematic outline of a grating-based HSI. A scene is focused on the sensor’s entrance slit. A filter passes a selected range of wavelengths, which are collimated and incident on a diffraction grating. The axis of diffraction is selected perpendicular to the orientation of the entrance slit. The diffracted slit image is focused on a focal plane: one axis corresponds to spatial position on the slit, the other axis is spectral. As the slit is scanned across the scene, multiple image frames are stacked to form a data cube.

Figure 11 “Pushbroom” HSI data collection. The instantaneous FOV of a nadir-oriented dispersive HSI collects spectral profiles for a spatial strip of pixels (a). The light collected over the time interval $T_{i-1/2}$ to $T_{i+1/2}$ constitutes a single frame of hyperspectral data. Multiple successive frames are concatenated to form a data cube (b). Note the position of the aircraft at three closely spaced times: observe that a single data frame contains photons from ground sample areas immediately behind ($T_{i-3}$) and in front of ($T_{i+3}$) the frame.

analysis methods that produce them are presented in section 6.
4.4 Livermore Imaging Fourier Transform Infrared Spectrometer: An Imaging Fourier Transform Spectrometer

The LIFTIRS is based on a Michelson interferometer fitted with an IR focal plane. A simplified diagram of this type of IFTS is presented in Figure 12. IR light from the observed scene is collimated and split into two paths. One path is equipped with a moving mirror so that the length of its optical path, \( x \), can be smoothly varied. Light from this path is recombined with light from the fixed-length path, forming an optical interference pattern. The pattern is a function of \( x \), and is focused on a GaSi image plane. The focal plane image an array of instantaneous samples of interferograms – one for each pixel – that cannot be interpreted without additional data frames. The optical path length, \( x \), is changed while successive frames are collected. At each spatial pixel the ordered set of interference amplitudes comprises the Fourier transform of the pixel’s spectral profile. An FFT applied to the data set produces a spectrum for each pixel. The performance parameters of LIFTIRS are listed in Table 3.

The distance traveled by the moving mirror determines the spectral resolution. A bandpass optical filter limits the measured spectral range, and the shortest wavelength passed by this filter determines how many frames need to be collected. Unlike filter- or dispersion-based HSI, an IFTS has adjustable spectral resolution. Scanning the mirror over a large span resolves fine spectral lines, which is desirable for detecting and discriminating the molecular vibrational and rotational transitions of gases. This is of particular use in the LWIR regime where many gaseous industrial by-products have spectral activity. In practice, sample noise increases with smaller resolved bandwidths, so the best signal-to-noise ratios are achieved when the IFTS bandwidth matches the line widths of gases being classified and discriminated.

A weakness of the IFTS is its sensitivity to random or periodic temporal fluctuations of pixel spectra. If these fluctuations fall within the bandwidth of the instrument, false spectral components are introduced while true components are destroyed. As an additional problem, an airborne IFTS requires very agile mounting systems to compensate for roll and pitch motion of the aircraft. Yaw motions (i.e. direction shifts) present a more difficult problem, introducing rotation within the image as data are collected. If successive image pixels do not correspond to the same point on the ground, spectral corruption is unavoidable.

Figure 13 illustrates the potential of the IFTS for gaseous pollution monitoring. A mixture of SF\(_6\) and NH\(_3\) was released from a stack at a test facility. The presence of both gases is detected using their characteristic absorption frequencies. Later, after the stack is purged for 15 min, the flow of SF\(_6\) is terminated, but to the surprise of the observers, substantial amounts of residual NH\(_3\) continue to be detected in the stack plume.

5 DATA CORRECTION

5.1 Types of Correction

Several data correction steps are required to properly capture the spectral content of a scene. Some of these corrections compensate for solar and atmospheric

Figure 13 LIFTIRS ground level observation of a gas plume. Two gases, (a) SF₆ and (b) NH₃, are released from a stack and easily detected at their characteristic absorption frequencies (946 and 966 cm⁻¹, respectively). The 980 cm⁻¹ sky background (c) is relatively uniform. (d) The measured spectral profile of the plume is the dark tracing, while reference spectra of SF₆ (946 cm⁻¹ peak) and NH₃ (928 and 966 cm⁻¹ peaks) are shown as lighter tracings. After a 15-min stack purge, no trace of SF₆ is detected (e), but the LIFTIRS team was surprised to find a persisting signature of NH₃ (f). This unexpected observation of residual NH₃ shows the power of HSI for monitoring gaseous pollutants. (Reproduced by permission of SPIE from C.L. Bennett et al., Proc. SPIE, Vol. 2480, 335–444, 1995.)

Effects while others handle the optical and electrical characteristics of an HSI sensor.

Let us follow a solar photon on its way from the sun to its information impact in an HSI data cube (Figure 14). The solar spectrum is essentially that of a blackbody at 5800 K with embedded absorption lines. Passing into the atmosphere, solar radiation is both absorbed and scattered. Gases such as oxygen, ozone and carbon dioxide are strong absorbers, but water vapor is by far the most significant gas affecting solar illumination at ground level. Light interacting with air molecules causes Rayleigh scattering, especially towards the blue end of the spectrum. Aerosols and particulate matter in the atmosphere produce Mie scattering, which acts over a wider spectral range. Clouds attenuate or completely block sunlight from illuminating a patch of ground. In addition to direct sunlight, skylight (i.e. scattered and refracted sunlight) and light reflected off nearby landscape also contribute illumination at ground level. At mid-IR wavelengths, hot objects such as running engines or motor exhaust, contribute photons to the scene. At long-IR wavelengths thermal emissions from ambient temperature objects and landscape also contribute.¹

At ground level the elements in the scene selectively absorb or reflect incident photons. Many natural materials have a substantial Lambertian component (Lambertian surfaces have no preferred direction of reflection), and have low to mid-range reflection coefficients (0 to 20%). Some materials such as snow, ice and water, as well as many man-made materials like metal and glass, possess substantial specular reflection properties; that is, they behave somewhat like mirrors. At certain angles light glints from strong specular reflectors can saturate a sensor designed for viewing Lambertian materials.

The reflected spectra of surface features pass through a span of atmosphere to the HSI sensor. Along the way, atmospheric absorption and scattering again contribute their effects. Unwanted light is scattered into the HSI’s optical path from the sun, skylight and light reflected from adjacent landscape features. Finally, thermal inhomogeneities in the atmosphere cause subtle lensing perturbations that disrupt the wavefront of reflected light.

Light reaching the sensor is absorbed, reflected or scattered to some extent by optical elements. These elements also introduce geometric and chromatic aberrations, and possibly image ghosts. The diffraction limit of the optical device constrains how sharply the image can be focused on the photo-active plane. Further, shot noise is produced in the detector due to statistical fluctuations in photon flux. The focal plane has opto-electrical characteristics that affect data collection: frequency-dependent quantum conversion efficiency, inactive “dead” pixels, “hot” or fluctuating pixels, individual pixel gains and offsets, electrical echoes, readout noise, limited dynamic range, quantization noise, 1/f noise (i.e. drift), and dark current. For LWIR sensors, uncooled optical elements of the sensor and enclosure components emit radiation, contributing to the measured signal. A thorough pre-collection calibration regimen is essential to characterize and minimize the effects of imperfect optics and electronics. During data collection itself periodic measures of the focal plane’s radiometric gains and offsets are needed to handle the inescapable drift of sensor responsivity and dark current. Further calibration is needed to check the HSI’s optical path relative to the platform’s pointing
direction and to properly assign spectral bands to specific focal plane rows. Airborne instruments without fully stabilized mounts are subject to unavoidable roll, pitch and yaw motions that cause image distortion. In regard to data fusion tasks, if the sensor is not pointing straight down (i.e. in the “nadir” viewing direction), the oblique viewing angle will introduce geometric distortions and image re-sampling will be required to correct the image.

Corrections for these effects can be accomplished with varying degrees of success. The most difficult tasks in remote sensing are characterizing the incident light at the surface, and properly correcting for the atmospheric effects of absorption and scattering. While these can have huge effects on spectral analysis algorithms, we are becoming increasingly adept at handling these issues, and are able to calculate the corrections at an acceptable rate using present day workstations.

5.2 Computing a Reflectance Data Cube

Spectral reflectance, the ratio of reflected to illuminating radiance, is an intrinsic property of materials, which makes it an attractive feature on which to base classification and quantification algorithms. Most natural objects have a slightly glossy surface. The specular characteristics of their surfaces are apparent for a narrow range of viewing angles relative to the illuminating source. For the purposes of remote sensing, the specular aspects of most materials can be set aside because observing conditions are usually chosen to minimize their contribution.

Calculating surface reflectance by remote observation is a challenging problem. Figure 15 shows the process of generating a reflectance data cube from raw data. The difficulties arise primarily from two sources: sensor drift and atmospheric effects. For sensors the “offset” (also called “dark current” or “background count”) tends to drift over time as $1/f$ noise. Generally, the longer the wavelength being monitored, the more this drift affects the measurement. In order to calculate a radiometrically correct data cube, a “dark field” (i.e. sensor frames recorded with the shutter closed) is recorded immediately before or after data collection.

Atmospheric effects are the most difficult aspect of calculating reflectance data cubes because many required parameters are difficult to obtain. Figure 14 illustrates the complicated phenomenology that is involved. Water vapor is a strong atmospheric absorber and varies in concentration laterally over tens of meters (GSD). Ozone concentration also varies substantially in the lower atmosphere near cities. Sophisticated atmospheric modeling programs such as MODTRAN can be used for calculating atmospheric optical behavior once key parameters are available. Extracting these parameters directly from spectral data is a goal of current algorithmic development. For example, ATREM (Atmospheric Removal Program) uses the absorption ratios of water bands to estimate atmospheric humidity on a pixel by pixel basis. Other approaches also include scattering phenomena and use recursive data smoothing and eigenvalue analysis.

Calculating a reflectance data cube begins by measuring the sensor gain profile for each pixel in the detector array (or at least verifying the profile obtained in laboratory tests). An on-board calibration source is essential. Both a dark field (D in Figure 15) and calibration “white field” (C) are collected. The radiometric power of the calibration source, $P_{\text{cal}}$, is accurately known from
HYPERSPECTRAL REMOTE SENSING: DATA COLLECTION AND EXPLOITATION

13

Figure 15 Process of calculating a reflectance data cube from raw data.

laboratory measurements. The gain coefficient for each focal plane pixel, G – the conversion factor from focal plane electron counts to radiometric quantification – is calculated using Equation (1) (see Figure 15):

\[ G = \frac{P_{cal}}{P} \tag{1} \]

This value of G for a given pixel will vary with wavelength, reflecting the frequency dependence of the detector’s quantum efficiency. Other factors affect G, such as inhomogeneities in the focal plane’s fabrication and its readout electronics. Unlike dark current, G should not change rapidly over time.

Converting a raw data cube to a reflectance data cube proceeds as outlined in Figure 15. The associated dark field offset, D, is subtracted from the raw data cube, \( S_0 \), and gain correction is applied. Bad focal plane pixels are noted, and the spectral alignment is confirmed by noting the pixel positions associated with key atmospheric absorption lines. This produces a radiometrically correct data cube.

The next step is to remove atmospheric perturbations. An atmospheric model is used to calculate the transmission profile of the optical path between the surface and the HSI sensor, \( T_R \). Similarly, the ground-level solar illumination spectrum, \( T_S I_0 \), is computed based on our best knowledge of atmospheric parameters. With these transmission profiles in hand, the reflectance data cube, \( S_5 \), is calculated using Equation (2):

\[ S_5 = \frac{(S_0 - D)G}{T_R T_S I_0} \tag{2} \]

6 SPECTRAL SCENE ANALYSIS

Hyperspectral image analysis is often concentrated on the problem of classification, i.e. detection and identification of a particular target or surface cover type. However, HSI allows for more than simple classification of image pixels. Analysis techniques have been developed that produce quantitative estimates of material abundance in a hyperspectral scene. Because such a wide variety of applications are addressed with this technology, hyperspectral analysis methods also vary widely and include techniques for spectral matching and feature fitting, linear and nonlinear unmixing, and structural modeling.

In general, a hyperspectral data cube is an image of some portion of the earth’s surface, in which a spectral reflectance curve is associated with each pixel in the image. In some instances, a pixel is homogeneous in the sense that the area of ground represented by that pixel contains only one type of material. However, most natural surfaces do not consist of a single uniform material, and a pixel can cover a spatial area containing different materials, each with its own individual spectral signature. In this case, the pixel will not contain a pure spectrum but a mixture of individual component
spectra, and the pixel is termed mixed. The spectrally unique signatures that combine to produce the statistically significant variations and mixtures in a hyperspectral image are called endmembers. Many hyperspectral image processing algorithms address the problems of accurate image endmember determination, separation of endmembers from background spectra, and estimation of endmember abundance.

6.1 Spectral Matching

A spectral angle mapper (SAM) is used to correlate measured spectra with a library of endmember spectra. The method can be used to detect targets in known or unknown backgrounds and to classify materials in an image. SAM treats spectra as vectors in $N$-dimensional space, where $N$ is the number of spectral bands per pixel, and matches pixels to reference spectra by computing angles in $N$-dimensional space. Let $\mathbf{u}$ and $\mathbf{r}$ be vectors of length $N$ representing an unknown and a reference spectrum, respectively. SAM determines the similarity of $\mathbf{u}$ to $\mathbf{r}$ through computation of the angle $a$ between them, as shown in Equation (3):

$$a = \cos^{-1}\left(\frac{\mathbf{u}^T \mathbf{r}}{||\mathbf{u}|| ||\mathbf{r}||}\right)$$

(3)

If the two spectra are similar, the angle $a$ between them will be small.

Using SAM, an image is classified by first calculating spectral angles between each image pixel and each reference spectrum, then assigning the pixel to the material class whose reference spectrum produces the best match, i.e. the smallest spectral angle. The reference spectra can come from a library of materials assumed to be in the scene or from the image itself. Figure 16 shows a hyperspectral image of an agricultural region near a river bend that has been classified using the SAM algorithm. In this case, material classes correspond to seven different land cover classes. The reference spectra were chosen from the image itself, and those pixels that did not generate small enough angles with the reference spectra were left unclassified (the black regions of the classified image). For this image, the SAM technique produced an accurate classification of river water depth as well as land cover types.

Because SAM depends on angles between spectral vectors and not the lengths of these vectors, the algorithm is insensitive to variations in illumination across a scene. This technique is useful for classification of general land cover types and even lends itself well to applications that require image analysis in real-time. However, more sophisticated processing is necessary to estimate material abundance and to deal with issues such as mixed pixels.

Another technique that is used to correlate a signature of interest with measured data is spectral matched filtering. This method is particularly useful for target detection in hyperspectral images and is based on well-known techniques in signal detection. Let $\mathbf{d}$ be a vector representing the target signature of interest and $\mathbf{p}$ an image pixel. The matched filter output, which is the vector dot product $\mathbf{d}^T \mathbf{p}$, gives a measure of how well the image pixel matches the desired signature. This technique has been extended to deal with the problem of detecting small targets in highly-structured backgrounds. In this case, an optimum matched filter is developed that takes into account the spatial as well as spectral variability of the image data and maximizes the probability of detecting a target at a particular false alarm rate. Adaptive matched filtering algorithms can be shown to achieve near-optimum performance for target detection without precise knowledge of target or background spectra.

6.2 Spectral Unmixing

Spectral unmixing techniques provide quantitative abundance estimates of individual component spectra in a hyperspectral scene. Unmixing is also used for detection of targets of interest, particularly at the sub-pixel level, and for removal of undesired signature components from hyperspectral measurements. The simplest model of a mixed pixel is a linear one. Research into mixing scales has indicated that linear mixing occurs when each individual photon encounters only one type of material before being reflected. Nonlinear mixing occurs when a single incident photon interacts with more than one material before being reflected. For example, the microscopic (or intimate) mixtures that are typical of many geologic situations engender nonlinearly mixed pixels. Even for the case of a nonlinear mixture model, a change of variables can linearize the unmixing problem, yielding a first-order approximation of endmember abundance.

Figure 16 A hyperspectral image classified using the SAM algorithm. (Color key: red, white – vegetation types 1 and 2; green – scrub; purple – bare soil; yellow – river sand; light blue – shallow river water; dark blue – deeper river water; black – unclassified pixels.)
The linear mixture model is described as follows. Let \( \mathbf{p}_i \) be an \( l \times 1 \) vector denoting the \( i \)th pixel in a hyperspectral image, where \( l \) is the number of spectral bands, and suppose there are \( k \) endmembers of interest in the scene. That is, there are \( k \) different classes of materials represented in the hyperspectral image. We will let \( \mathbf{M} \) denote the \( l \times k \) matrix whose columns contain the endmember signatures of interest, and \( \mathbf{a}_i = (a_{i1}a_{i2} \cdots a_{ik})^T \) be a \( k \times 1 \) abundance vector, where \( a_{ij} \) denotes the fraction of the \( j \)th signature in the pixel \( \mathbf{p}_i \). The mixed pixel is then modeled as shown in Equation (4):

\[
\mathbf{p}_i = \mathbf{Ma}_i + \mathbf{n}
\]

where \( \mathbf{n} \) is an \( l \times 1 \) vector representing noise which we will assume here to be Gaussian with zero mean and covariance \( \sigma^2 \mathbf{I} \) (\( \mathbf{I} \) is the \( l \times l \) identity matrix).

The unmixing problem is to estimate the spectral abundance vector \( \mathbf{a}_i \) given the observation \( \mathbf{p}_i \). For the model described above, the maximum likelihood estimate is also the least squares estimate of \( \mathbf{a}_i \), and is given by Equation (5):

\[
\hat{\mathbf{a}}_i = (\mathbf{M}^T \mathbf{M})^{-1} \mathbf{M}^T \mathbf{p}_i
\]

provided there are no constraints placed on the components of \( \hat{\mathbf{a}}_i \). Therefore, \( \hat{\mathbf{a}}_i \) is an unconstrained estimate of the fractional abundance of each endmember in pixel \( \mathbf{p}_i \).

Figure 17 shows an example of linear spectral unmixing for a hyperspectral image of the Cuprite, Nevada region. The colors correspond to the fractional abundance of six endmembers for each individual pixel.

The accuracy of an abundance estimate derived by spectral unmixing depends directly on the chosen matrix of endmembers, which come from the image itself, from libraries of laboratory or field measurements, or from estimates of target and background signatures. A number of automatic and manual endmember selection techniques have been developed including construction of endmembers from the dominant eigenvectors of a principal component analysis of the image, or formulation of the endmember selection process as a problem in convex geometry.\(^{47,55,56}\) Automated endmember selection methods yield rapid, repeatable processing of large volumes of data and have been implemented for real-time analysis of hyperspectral imagery.\(^{57}\) Manual techniques are useful for interactive exploration of the high-dimensional data space spanned by the spectra in a hyperspectral cube.\(^{58}\) Each technique for endmember determination has its own advantages and drawbacks, and the choice of method depends strongly on the imaging application.

The analysis techniques described above are representative of the core methods that have been developed for hyperspectral image classification and material identification. Since the applications for hyperspectral technology are wide ranging and this field of study has become increasingly active in recent years, there are of course many aspects of this work that have not been described here. For example, there have been significant advances in the areas of vegetation structural modeling, foliar chemistry analysis from hyperspectral images, hyperspectral data compression and real-time processing. The reader is encouraged to explore the references for details of this research.

7 FUTURE DEVELOPMENTS

The field of HSI, including instrumentation and analysis, has grown significantly in the last decade. Recent developments in focal plane array technology, high-speed data acquisition and processing hardware, and increasingly accurate analysis techniques have enabled the growth of HSI as a quantitative remote sensing tool. Although the technology has advanced greatly, future developments could result in increased utility of HSI. For example, larger focal plane arrays and faster data acquisition hardware could allow for even wider area coverage with high spatial, as well
as spectral, resolution. Another aspect of the technology that will soon see advancements is HSI of the earth from space. At the time of writing, NASA is preparing a hyperspectral instrument payload for launch within 1 year. This first hyperspectral look at the earth from space will generate exciting new developments in this quickly evolving and expanding branch of remote sensing.

REFERENCES

Reflectance and emittance spectra have been used for many years to obtain compositional information about the Earth’s surface. Electronic transition and charge transfer processes associated with transition-metal ions such as Fe, Ti, Cr, and so on produce diagnostic absorption features in the visible and near-infrared (VNIR) wavelength region of the spectra of minerals and rocks, while vibrational processes in H₂O and OH⁻ produce fundamental overtone absorptions in the shortwave infrared (SWIR) portion of the spectrum. Field and laboratory studies have demonstrated that reflectance spectroscopy can be used for mineral identification and further geological studies. The translation of these measurements to imaging data led to the development of the field of imaging spectrometry in remote sensing. Imaging spectrometers acquire images in a large number of narrow contiguous spectral bands to enable the extraction of reflectance spectra at a pixel scale that can be directly compared with similar spectra measured either in the field or in a laboratory. In this chapter, the use of imaging spectrometer data for geological applications is discussed by describing the processing chain of data analysis from the raw data acquisition to prospective applications. Several topics are addressed. An appraisal of future spaceborne imaging spectrometer missions and potential prospective applications provides insight into this vastly growing field of research.

**1 INTRODUCTION AND HISTORICAL PERSPECTIVE**

**1.1 Objectives of Imaging Spectrometry**

When light interacts with a mineral or rock, light of certain wavelengths is preferentially absorbed while light of other...
wavelengths is transmitted in the substance. Reflectance, defined as the ratio of the intensity of light reflected from a sample to the intensity of the light incident on it, is measured by reflection spectrophotometers which are composed of a light source and a prism to separate light into different wavelengths. The light beam interacts with the sample and the intensity of reflected light at various wavelengths relative to a reference standard of known reflectance is measured by a detector. Thus a continuous reflectance spectrum of the sample is obtained in the wavelength region measured.

Reflectance spectra have been used for many years to obtain compositional information about the Earth’s surface. Similarly, it has been shown that spectral reflectance in the VNIR offers a rapid and inexpensive technique for determining the mineralogy of samples and obtaining information about chemical composition. Electronic-transition and charge-transfer processes (e.g. changes in the energy states of electrons bound to atoms or molecules) associated with transition-metal ions such as Fe, Ti, Cr, and so on, largely determine the position of diagnostic absorption features in the VNIR wavelength region of the spectra of minerals.\(^1\)\(^-\)\(^3\) In addition, vibrational processes (e.g. small displacements of the atoms about their resting positions) in H\(_2\)O and OH\(^-\) produce fundamental overtone absorptions.\(^4\)\(^,\)\(^5\) Electronic transitions produce broad absorption features that require higher energy levels than do vibrational processes and therefore take place at shorter wavelengths.\(^4\)\(^,\)\(^6\) The position, shape, depth, and width of these absorption features are controlled by the particular crystal structure in which the absorbing species is contained and by the chemical structure of the mineral. Thus, variables characterizing absorption features can be directly related to the mineralogy of the sample.

Remote sensing (e.g. the observation of a target by a device separated from it by some distance and thus without physical contact) of the surface of the Earth from aircraft and from spacecraft provides information not easily acquired by surface observations. Until recently, the main limitation of remote sensing was that surface information lacked detail owing to the broad bandwidth of sensors available. Work on high-spectral-resolution radiometry has shown that earth surface mineralogy can be identified using spectral information from sensor data.\(^6\) Conventional sensors (e.g. Landsat multispectral scanner (MSS) and thematic mapper (TM), and Système Probatoire de l’Observation de la Terre (SPOT)) acquire information in a few separate spectral bands of various widths (typically in the order of 0.1–0.2 \(\mu\)m), thus smoothing to a large extent the reflectance characteristics of the surface.\(^7\) Most terrestrial materials are characterized by spectral absorption features typically 0.02–0.04 \(\mu\)m in width.\(^8\) High-spectral-resolution remotely sensed images are acquired to produce reflectance or radiance spectra for each pixel in the scene. Imaging spectrometers acquire images in a large number (typically over 40) of narrow (typically 0.01–0.02 \(\mu\)m in width) contiguous (i.e. adjacent and not overlapping) spectral bands to enable the extraction of reflectance spectra at a pixel scale that can be directly compared with similar spectra measured either in the field or in a laboratory. Different names have been coined for this field of remote sensing including “imaging spectrometry”, “imaging spectroscopy” and “hyperspectral remote sensing”. Although they have a different meaning in the sense of a direct translation of the term (i.e. spectrometry for “measuring”, spectroscopy for “seeing”, hyperspectral for “too many bands”), the significance and perception to the remote sensing community is the same: “the acquisition of images in hundreds of registered, contiguous spectral bands such that for each picture element of an image it is possible to derive a complete reflectance spectrum”\(^9\) (Figure 1).

The objective of imaging spectrometry is to measure quantitatively the components of the Earth system from calibrated spectra acquired as images for scientific research and applications. Thus it is of interest to measure physical quantities at the Earth surface such as upwelling radiance, emissivity, temperature, and reflectance. Based upon the molecular absorptions and constituent scattering characteristics expressed in the spectrum we seek to:

- detect and identify the surface and atmospheric constituents present;
- assess and measure the expressed constituent concentrations;

![Figure 1](Image 328x149 to 540x313)
IMAGING SPECTROMETRY FOR GEOLOGICAL APPLICATIONS

- assign proportions to constituents in mixed spatial elements;
- delineate spatial distribution of the constituents;
- monitor changes in constituents through periodic data acquisitions;
- simulate, calibrate, and intercompare sensors;
- validate, constrain, and improve models.

Through measurement of the solar reflected spectrum, a wide range of scientific research and applications are being pursued using signatures of energy, molecules, and scatterers in the spectra measured by imaging spectrometers. These fields include:

- atmosphere: water vapor, cloud properties, aerosols, absorbing gases;
- plant ecology: including chlorophyll, leaf water, lignin, cellulose, pigments, structure, vegetation species and community maps, nonphotosynthetic constituents;
- geology and soils: including mineralogy, soil type;
- coastal and inland waters: including chlorophyll, plankton, dissolved organics, sediments, bottom composition, bathymetry;
- snow and ice hydrology: including snow cover fraction, grainsize, impurities, melting;
- biomass burning: including subpixel temperatures and extent, smoke, combustion products;
- environmental hazards: including contaminants directly and indirectly, geological substrate;
- calibration: including aircraft and satellite sensors, sensor simulation, standard validation;
- modeling: including radiative transfer (RT) model validation and constraint;
- commercial: including mineral exploration, agriculture and forest status;
- algorithms: including autonomous atmospheric correction, advanced spectra derivation;
- other: human infrastructure, mine detection, and so on.

1.2 History of Imaging Spectrometry

The first civilian airborne spectrometer data were collected in 1981 using a one-dimensional profile spectrometer developed by the Geophysical Environmental Research (GER) Company which acquired data in 576 channels covering the 0.4–2.5 µm wavelength range followed by the Shuttle Multispectral Infrared Radiometer (SMIRR) in 1981. The first imaging device was the Fluorescence Line Imager (FLI; also known as the Programmable Line Imager, PLI) developed by Canada’s Department of Fisheries and Oceans (in 1981) followed by the Airborne Imaging Spectrometer (AIS), developed at the NASA (National Aeronautics and Space Administration) Jet Propulsion Laboratory which was operational from 1983 onward. This instrument acquired data in 128 spectral bands in the range of 1.2–2.4 µm with a field-of-view (FOV) of 3.7 degrees resulting in images of 32-pixels width. A later version of the instrument, AIS-2, covered the 0.8–2.4 µm region acquiring images 64 pixels wide. In 1987 NASA began operating the Airborne Visible/Infrared Imaging Spectrometer (AVIRIS). AVIRIS was developed as a facility that would routinely supply well-calibrated data for many different purposes. The AVIRIS scanner makes possible the simultaneous collection of images in 224 contiguous bands resulting in a complete reflectance spectrum for each 20 x 20 m pixel in the 0.4–2.5 µm region with a sampling interval of 10 nm. The FOV of the AVIRIS scanner is 30 degrees resulting in a ground FOV of 10.5 km. Private companies now recognize the potential of imaging spectrometry resulting in several sensors becoming available for specific applications. Examples are the GER Company imaging spectrometer that became operational in 1986 and the Compact Airborne Spectrographic Imager (CASI) that became operational in 1989. Currently many space agencies and private companies in developed and developing countries operate their own instruments.

In this article, the use of imaging-spectrometer data for geologic applications is discussed by describing the processing chain of data analysis from the raw data acquisition all the way through to the prospective applications. The following topics are addressed:

- physics of reflectance and emittance spectroscopy;
- airborne and spaceborne instruments;
- data acquisition and (spectral, spatial, noise adjustment) preprocessing;
- radiance to (absolute and relative) reflectance correction;
- data-analysis techniques; and
- geological applications (mineral and lithological mapping, geobotanical studies, environmental studies, petroleum-related studies, atmospheric geology, volcanology and thermography).

2 PHYSICS OF REFLECTANCE AND EMITTANCE SPECTROSCOPY

2.1 Physics of Radiation

Thermal radiation is emitted by all objects at temperatures above absolute zero. Consider an area dA and radiation arriving from a direction θ to the normal of dA, but in the range of directions forming a solid angle of dΩ steradians. Radiance, L in W m⁻² sr⁻¹, is defined by
Equation (1) as
\[
d\Phi = L \, dA \, d\Omega \cos \theta
\]
where \( d\Phi \) is the total power incident on \( dA \). The total power falling on \( dA \) from all directions is given by the integration over \( 2\pi \) steradians for the case of no absorption or scattering by Equation (2)
\[
\Phi = dA \, L \cos \theta \, d\Omega = E \, dA
\]
where \( E \) is the irradiance measured in \( \text{W m}^{-2} \). In the reverse case when \( E \) measures the total radiance leaving \( dA \) we refer to exitance, \( M \), and the total power emitted by the source is the radiant intensity, \( I \), defined in Equation (3) as
\[
\Phi_{\text{total}} = I \, d\Omega
\]
We can also express these quantities spectrally by introducing an interval of wavelength \( \lambda \) and integrating over \( d\lambda \). Spectral radiance according to Planck’s relationship is given in Equation (4) by
\[
L_\lambda = \frac{2hc^2}{\lambda^5} (e^{hc/\lambda kT} - 1)^{-1}
\]
where \( h \) is Planck’s constant, \( k \) is Boltzmann’s constant (1.38 \times 10^{-23}\text{ J K}^{-1}), \( c \) is the speed of light (in a vacuum) and \( T \) is the temperature. The total outgoing radiance of a blackbody of temperature \( T \) is given in Equation (5) by
\[
L = \int_0^\infty L_\lambda \, d\lambda = \frac{2\pi^4 k^4}{15c^2 \hbar^3} T^4
\]
where \( \sigma = 2\pi^4 k^4/(15c^2 \hbar^3) \) is known as Stefan–Boltzmann’s constant (5.67 \times 10^{-8}\text{ W m}^{-2}\text{K}^{-4}). Wien’s displacement law gives the relation between the wavelength at which the maximum radiation is reached, \( \lambda_{\text{max}} \), and the temperature of the blackbody as, Equation (6)
\[
\lambda_{\text{max}} = \frac{c_w}{T}
\]
where \( c_w \) is a constant (Wien’s constant) of 2.898 \times 10^{-3}\text{ K m}.

When radiation interacts with a surface, it is partly absorbed into the substance and partly scattered or reflected by the object. Consider a collimated beam of radiation incident on a surface at an incidence angle \( \theta_0 \). The irradiance \( E \) is given by \( F \cos \theta_0 \), where \( F \) is the flux density, and scattered into a solid angle \( d\Omega \) in a direction \( \theta_1 \). The outgoing radiance of the surface as a result of this illumination is \( L_1 \) in the direction \( (\theta_1, \phi_1) \) where \( \phi_1 \) is the azimuthal angle. The bidirectional reflectance distribution function (BRDF) \( R \) (in \text{sr}^{-1}) is defined in Equation (7) as
\[
R = \frac{L_1}{E}
\]
where \( R \) is a function of the incident and scattered directions and can thus be noted as \( R(\theta_0, \phi_0, \theta_1, \phi_1) \). The reflectivity of the surface, \( r \) (also known as albedo), is the ratio of the total power scattered to the total power incident given in Equation (8) as
\[
r(\theta_0, \phi_0) = \frac{\pi}{2} \int_{\theta=0}^{\pi/2} \int_{\phi=0}^{2\pi} R \cos \theta_1 \sin \theta_1 \, d\theta_1 \, d\phi_1
\]
Two extreme cases of scattering surface can be defined: the perfectly smooth surface (specular surface) and the perfectly rough surface (the Lambertian surface). A perfect Lambertian surface will scatter all the radiation incident upon it so that the radiative exitance \( M \) is equal to the irradiance \( E \) and the albedo is unity. A measure of roughness of a surface is given by the Rayleigh criterion. For a surface to be smooth according to the Rayleigh criterion it should satisfy Equation (9)
\[
\frac{\Delta h \cos \theta_0}{\lambda} < \frac{1}{8}
\]
where \( \Delta h \) is the surface irregularity of height and \( \lambda \) the wavelength considered.

### 2.2 Reflectance Spectroscopy

Radiation incident on a material is preferentially absorbed by molecules forming the structure of the substance at wavelengths predetermined by quantum-mechanical principles. The total energy of a molecule \( W_t \) is the sum of the electronic energy \( W_e \), the vibrational energy \( W_v \) and the rotational energy \( W_r \) given in Equation (10) as
\[
W_t = W_e + W_v + W_r
\]
Changes in energy states of molecules due to changes in rotational energy levels do not occur in solids and will not be treated here further. This discussion is restricted to changes in electronic states and vibrational processes. Harmonic vibration is described by Equation (11)
\[
w_v = \frac{f(m_1 + m_2)}{m_1 m_2}
\]
where \( f \) is the restoring force constant (spring constant), \( v \) the vibrational states \( v = 0, 1, 2, \ldots \) and \( m_1 \) and \( m_2 \) are the masses of the molecule. The possible energy states of the harmonic vibration are given by quantum mechanics
in Equation (12) as

$$W_v = (v + \frac{1}{2}) \hbar \omega_v$$

where $\hbar$ is Planck’s constant equal to $6.6 \times 10^{-34}$ W s. These define the spectral regions where absorption can occur as a result of vibrational processes (Figure 2).

Electrons in solids can occupy a discrete number of energy levels $q = 0, 1, 2, \ldots$. When photons are incident on a material they interact with the electrons, and the absorption of a photon of a proper energy $\hbar \omega$ may cause the transition of the electron to a higher state. Absorption of energy into the medium results in a change in the system. Absorption of a photon of proper energy $\hbar \omega$ may cause the transition of an electron from orbital $q = 0$ to $q = 1$ corresponding to an energy difference given in Equation (15) of

$$\Delta W = W_{(N/2+1)} - W_{N/2} = \frac{\hbar^2}{8mL^2}(N + 1)$$

(Acknowledging that $\hbar = h/c$, where $c$ is the speed of light (in a vacuum) and $\lambda$ is the wavelength at which the absorption occurs, we can find the longest wavelength $\lambda_{max}$ which can be absorbed by the molecule owing to the first transition as, Equation (16)

$$\lambda_{max} = \frac{8mc^2}{\hbar N + 1}$$

To be able to interpret or predict the wavelengths at which absorptions due to electronic transitions occur it is useful to know the energy level schemes of the molecules involved in the transitions. Reflectance spectra of minerals are well known and several studies have been conducted to determine reflectance spectra of rocks. The reflectance characteristics of rocks can be simulated accurately by studying the compound effect of reflectance of minerals in a spectral mixture forming the rock. Reflectance spectra of mineral mixtures are a systematic combination of the reflectance of the pure mineral components or end-members in the mixtures. Several investigators have examined the systematics of minerals theoretically and empirically, and found that if the scale of mixing is small, or macroscopic, the spectral systematics of mixing different materials are linear while for microscopic or intimate mixtures the systematics are nonlinear.

Mathematical models for the analysis of reflectance spectra of mineral mixtures and rocks have been presented by many workers. Examples of minerals showing absorption features in the near-infrared (NIR) due to electronic transition processes are shown in Figure 3 while Figure 4 shows some minerals with characteristic absorption features in the SWIR due to vibrational processes. Figure 5 shows reflectance curves of rocks in the thermal electromagnetic (EM) region.

Reflectance spectra of minerals measured by different spectroradiometers with different spectral resolution are stored in spectral libraries that are available in digital format (e.g. Grove et al., Clark et al.). A large variety of spectroradiometers now exist that measure the visible (VIS)/SWIR part of the spectrum (e.g. Smith, Curtiss and Goetz, Pearson et al., and Analytical Spectral Devices at http://www.asdi.com/) and/or the middle infrared/thermal infrared (MIR/TIR) wavelength range.
Figure 3 Spectra of (a) goethite and (b) hematite showing diagnostic absorption features short of 1.0 \( \mu \text{m} \) due to electronic transitions.

Figure 4 Spectra of minerals characterized by diagnostic absorption features due to vibrational processes: (a) montmorillonite (1.4 and 1.9 \( \mu \text{m} \) due to H\(_2\)O), (b) kaolinite (1.4 \( \mu \text{m} \) due to OH), (c) alunite (2.2 \( \mu \text{m} \) due to Al–OH), (d) talc (2.3 \( \mu \text{m} \) due to Mg–OH), and (e) calcite (2.34 \( \mu \text{m} \) due to CO\(_3\)).

Figure 5 Directional hemispherical reflectance spectra of fresh rock.

(e.g. Hoover and Kahle). Similar spectral libraries are available for vegetation (e.g. Elvidge) and soils (e.g. Baumgardner et al., Condit). Emissivity of terrestrial materials (i.e. minerals, rocks, soils, vegetation) in the thermal atmospheric window has been recorded and stored in a data base by Salisbury and D’Aria partly based on earlier studies by Buettner and Kern, Elvidge, Lyon, Pinkley and Williams, Salisbury and D’Aria, Salisbury and Milton, Salisbury and Walter, Schaaf and Williams, Vincent et al., Walter and Salisbury, and Wong and Blevin. Further studies on this topic can be found in Salisbury and Henderson et al.
3 AIRBORNE IMAGING SPECTROMETER SYSTEMS

3.1 Overview

It is impossible to describe all currently operational AIS systems in detail. An attempt to provide and maintain an overview of sensors resulted in “Michael Schaepman’s comprehensive list of imaging spectrometers” at http://www.geo.unizh.ch/~schaep/research/apex/IS_list.html. This contains a list of 45 (on 22 July 1998) airborne and spaceborne imaging spectrometer systems including a rudimentary description of their characteristics. A similar list is provided at http://www.eol.ists.ca/documents/IS-team-canada/ and in Staenz. In the section on the “History of imaging spectrometry” an overview of development that led to some of the currently operational airborne systems is given. I provide a basic description here of two systems, AVIRIS, and Digital Airborne Imaging Spectrometers (DAIS) 7915, in order to give examples of the type and amount of data that is provided by these systems. In Table 1, a selection of sensors that are often used for geologic imaging spectrometry studies are listed.

3.2 Airborne Visible/Infrared Imaging Spectrometer

AVIRIS delivers calibrated images of the upwelling spectral radiance in 224 contiguous spectral channels with a wavelength-sensitive range of 10 nm nominal width in the 0.4–2.5 μm wavelength region. The instrument is operated aboard NASA’s ER-2 airplane (a modified U2) at approximately 20 km above sea level with an average airspeed of about 730 km hr⁻¹. AVIRIS uses a scanning mirror to sweep back and forth (whiskbroom scanning), producing 614 pixels for the 224 detectors for each scan. Each pixel produced by the instrument

covers an approximately 20 m² area on the ground (with some overlap between pixels), thus yielding a ground swath about 11 km wide. The ground data is recorded on board the instrument along with navigation and engineering data and the readings from the AVIRIS on-board calibrator.

Some details of the instrument are as follows:

- mass: 340 kg;
- encoding: 10 bit data encoding through 1994, 12 bit from 1995;
- spectrometers: four grating spectrometers (A, B, C, D);
- detectors: silicon (Si) detectors for the visible range; indium–antimonide (InSb) detectors for the NIR;
- scanning: whiskbroom scanning with 12 Hz scanning rate;
- bandwidth: 10 nm nominal, calibrated to within 1 nm;
- FOV (field-of-view): 30 degrees total FOV (full 614 samples);
-IFOV (instantaneous field-of-view): 1 mrad IFOV, calibrated to within 0.1 mrad.

More details on AVIRIS can be found in Vane et al. and Green et al. (55)

### 3.3 Digital Airborne Imaging Spectrometer (7915)

Fundied by the European Union, DLR (Deutsche Forschungsanstalt für Luft-und Raumfahrt e.V.) operates the 79-channel DAIS 7915(56) built by the GER Company. This sensor, which is the successor of the 63-channel GERIS, covers the spectral range from the visible to the thermal infrared (TIR) wavelengths at variable spatial resolution from 3 to 20 m depending on the carrier aircraft flight altitude. Six spectral channels in the 8–12 µm region could be used for the retrieval of temperature and emissivity of land surface objects. These and 72 narrow-band channels in the atmospheric windows (e.g., those wavebands that pass relatively undiminished through the atmosphere) between 0.450 and 2.45 µm allow investigation of land surface processes with a special emphasis on vegetation/soil interactions. The instrument has four spectrometers covering the 4–12.6 µm wavelength range as follows:

- spectrometer 1: 0.4–1.0 µm 32 bands bandwidth = 15–30 nm detector: Si;
- spectrometer 2: 1.5–1.8 µm 8 bands bandwidth = 45 nm detector: InSb;
- spectrometer 3: 2.0–2.5 µm 32 bands bandwidth = 20 nm detector: InSb;
- spectrometer 3: 3.0–5.0 µm 1 band bandwidth = 200 nm detector: InSb;
- spectrometer 4: 8.0–12.6 µm 6 bands bandwidth = 900 nm detector: mercury cadmium, telluride infrared (IR) detectors (MCT).

The main radiometric and geometric parameters include:

- dynamic range: 15 bit;
- sensitivity VNIR: NER (noise equivalent radiance) < 0.025 mW cm⁻² sr⁻¹ µm⁻¹
- SWIR: NER < 0.025 mW cm⁻² sr⁻¹ µm⁻¹
- MIR/TIR: NET (noise equivalent temperature) < 0.1 K;
- FOV: 0.894 rad (26 degrees) on DO 228, depending on aircraft max. 39;
- IFOV: 3.3 mrad (0.189 degrees);
- GIFOV: depending on aircraft altitude 5–20 m;
- scan frequency: adjustable according to aircraft altitude between 6–24 Hz;
- image pixels per line: 512.

More details can be found in Strobl et al. (58)

### 4 FUTURE PLANNED SPACEBORNE IMAGING SPECTROMETER SYSTEMS

A number of orbital imaging spectrometer missions are planned or being prepared currently. HIRIS, the High-resolution Imaging Spectrometer (NASA) is designed to acquire images in 192 spectral bands simultaneously in the 0.4–2.5-µm wavelength region with a ground resolution of 30 m and a swath width of 30 km. This scanner has a spectral resolution of 9.4 nm in the 0.4–1.0-µm wavelength region and a 11.7-nm spectral resolution in the 1.0–2.5-µm wavelength range. Though an interesting design, there are no plans for the HIRIS to fly. NASA is now supporting instead the Japanese Advanced Spaceborne Thermal Emission and Reflectance Radiometer (ASTER), a high-spectral-resolution imaging spectrometer planned for launch in 1999 on the EOS AM1 platform. The instrument is designed with three bands in the VNIR spectral range with a 15-m spatial resolution, six bands in the SWIR with a 30-m spatial resolution, and five bands in the TIR with a 90-m spatial resolution. The IR/VNIR and SWIR bands have a spectral resolution in the order of 10 nm. Simultaneously, a single band in the NIR will be provided along track for stereo capability. The swath width of an image will be 60 km with 136 km crosstrack and a temporal resolution of 16 days. Also on the EOS-AM1, the Moderate Resolution Imaging Spectroradiometer (MODIS) is planned as a land remote sensing instrument with high revisiting.
time. MODIS is mainly designed for global change research. The European Space Agency (ESA) are developing two spaceborne imaging spectrometers: The Medium-resolution Imaging Spectrometer (MERIS) and the High-resolution Imaging Spectrometer (ESA) (HRIS); now renamed PRISM, Process Research by an Imaging Space Mission. MERIS, currently planned as payload for the satellite Envisat-1 (see also http://www.esoc.esa.de/external/mso/envisat.html/) to be launched in 1999 by the Ariane 5, is designed mainly for oceanographic application and covers the 0.39–1.04-\(\mu\)m wavelength region with 1.25 nm bands at a spatial resolution of 300 m or 1200 m. PRISM, currently planned for Envisat-2 to be launched around the year 2000, is a spectrometer similar to HIRIS which will cover the 0.4–2.4-\(\mu\)m wavelength range with a 10 nm contiguous sampling interval at a 32 m ground resolution. The first satellite imaging spectrometer to be tested was the LEWIS Hyperspectral Imager (HSI) from the TRW company which was launched in 1997 but failed. It covered the 0.4–1.0-\(\mu\)m range with 128 bands and the 0.9–2.5-\(\mu\)m range with 256 bands of 5-nm and 6.25-nm bandwidth respectively. Several other instruments are in the design stage. The Chinese Imaging Spectrometer (CIS) will have 36 bands in the visible to SWIR wavelength region and the National Space Development Agency of Japan (NASDA) global imager (GLI). The Commonwealth Scientific and Industrial Research Organization (CSIRO) ARIES (Australian Resource Information and Environment Satellite) with 32 bands from 0.5 to 1.0\(\mu\)m and 32 bands from 2.0 to 2.5-\(\mu\)m is in the planning stage. Many private companies are exploring the possibility of developing and launching tailor-made instruments. An overview on these instruments, as well as any other review of currently available sensors, would be outdated and obsolete before publication.

5 DATA ACQUISITION AND PREPROCESSING OF IMAGING SPECTROMETER DATA

5.1 Overview

The chain of analysis steps carried out during preprocessing of imaging spectrometer data is described in this section. This generally is conducted by the manufacturers, institute/agency, or commercial company that maintains and operates the instrument. In most cases the user is provided with at-sensor radiance data and the necessary instrument characteristics (e.g. spectral response functions (SRFs), band passes, etc.) needed for further analysis. The on-ground calibration of a visible to thermal infrared (VIS/TIR) imaging spectrometer consists of a sequence of procedures providing the calibration data files and ensuring the radiometric, spectrometric, and geometric stability of the instrument:

- measurement of noise characteristics of the sensor channels;
- measurement of the dark current of the channels;
- measurement of the relative SRF of the channels;
- derivation of the effective spectral bandwidth of the channels;
- definition of the spectral separation of the channels;
- measurement of the absolute radiometric calibration coefficients (the “transfer functions” between absolute spectral radiance at the entrance to the aperture of the sensor and the measured radiation-dependent part of the output signal of each channel);
- definition of the NER and the noise equivalent temperature difference (NE\(\Delta\)T) of the channels;
- measurement of the IFOV, the spectral resolution and the deviations in the band-to-band registration.

A typical laboratory calibration facility for VIS/TIR wide-angle video spectrometric airborne sensors as found at DLR-Oberpfaffenhofen consists of the following four main parts:

1. spectrometric/geometric calibration part (SCP);
2. relative radiometric calibration part (RRCP);
3. thermal absolute calibration part (TACP);
4. absolute radiometric calibration part (ARCP).

Part 1 (SCP) comprises a mirror collimator with a flat folding mirror at the parallel-light output of the collimator. The mirror collimator has a focal length of 150 cm and a circular aperture of 30 cm diameter. At the focus position of the mirror collimator the following can be installed:

- the output slit of a monochromator for the 0.4–2.5 \(\mu\)m spectral region;
- the interference filter arrangement;
- different illuminated point or slit targets (for geometric calibration).

The flat folding mirror at the collimator output allows us to realize different illumination directions of the parallel light from the collimator output to the sensor entrance.

Part 2 (RRCP) is mobile and included because it is impossible to check the absolute radiometric calibration of the installed sensor by means of an integrating sphere (IS). The IS consists of an optical module and power supply unit. The optical module contains four halogen lamps of 100 W and several dissipative panels made of ground glass. The dimensions of the illuminated surface are 40 cm by 55 cm.
Part 3 (TACP) is mobile and consists of two water-cooled blackbodies, each with dimensions of 100 × 100 cm², one at ambient or up to 5°C below ambient temperature, the other at 25–30°C above ambient temperature, and the supply module. The TACP is used for the radiometric calibration of the mid-IR and the thermal channels of the sensor in the laboratory and in the hangar.

Part 4 (ARCP) is used for the absolute on-ground calibration of the sensor in the visible to shortwave infrared (VIS/SWIR) spectral region (0.4–2.5 µm) by means of an IS (IS; Figure 6). The interior of the IS (1.65 m in diameter) is coated with barium sulfate. The eighteen 200-W lamps are mounted internally. Each lamp has its own individual power supply, so that each may be lit independently, providing 18 equal steps of radiance. The maximum radiance of the IS is 0.08 mW sr⁻¹ cm⁻² nm⁻¹ at a wavelength of 1.0 µm. The homogeneity of the radiance at the 40 cm × 55 cm rectangular output part of the sphere is better than 1%, if at least four lamps are lit. The IS has to be calibrated from time to time by establishing the ratio between the output of the sphere and a well-known radiance standard, the so-called absolute diffuse source (ADS).

The following preprocessing steps are described in detail below:
- spectral calibration
- spatial calibration
- noise adjustment.

The following sections are derived from discussions with engineers and scientists involved in the calibration of AISs, a subject poorly covered in literature. Those seeking more details on these topics are referred to the following articles and book chapters: data acquisition (Goetz(67)); spectral calibration (Strobl, Goetz, Green, Green et al., Oertel et al., Strobl et al., Strobl et al., Strobl et al., Strobl et al.); geometric calibration and geocoding (Meyer(74)), and signal-to-noise calculation (Gao, Curran and Dungan(76)).

5.2 Spectral Preprocessing Chain

Data acquisition by imaging spectrometers can be done using the whiskbroom, pushbroom, or staring principle. Whiskbroom imagers are electromechanical scanners. On-axis optics or telescopes with scan mirrors sweep from one edge of the swath to the other. The FOV of the scanner can be detected by a single detector or a single-line-detector. Simultaneously the movement of the satellite or airplane guarantees the sweeping scan over the earth. This means that the dwell time for each ground cell must be very short at a given IFOV because each scan line consists of multiple ground cells which will be detected. In whiskbroom scanning each pixel is viewed separately which allows a wide FOV and only one detector in each spectral band needs to be calibrated. The disadvantage is the short dwell time (i.e. the time that the instrument “sees” each pixel), which limits the spatial and spectral resolution as well as the ratio of signal-to-noise. Furthermore, the rotating mirror often causes resonance that may be observed in the data as striping.

Pushbroom scanners are electronic scanners that use a line of detectors to scan over a two-dimensional scene. The number of pixels is equal to the number of ground cells for a given swath. The motion of the aircraft or the satellite provides the scan in the along-track direction, and thus the inverse of the line frequency is equal to the pixel dwell time. By using a two-dimensional detector, one dimension can represent the swath width (spatial dimension, y) and the other the spectral range. These imaging spectrometers can be subdivided into wide-field imagers (MERIS, ROSIS (Relative Optics System Imaging Spectrometer)) and narrow-field imagers (HSI, PRISM).

Staring imagers are also electronic scanners. They detect a two-dimensional FOV instantly. The IFOV along and cross track corresponds to the two dimensions of the detector area array. Two subgroups of staring imagers
are the wedge-imaging spectrometer (WIS) and thermal-delay integration imagers (TDIs). If the incoming light passes a linear wedge filter, each row of the ground segment is seized by the detector row for a determined wavelength. For very high ground resolution and low-sensitivity applications, \( n \) rows of the ground can be traced by using a TDI. The light from the scene will be separated by a linear filter for spectral band definition. On the two-dimensional detector the signal for this line can be read out from multiple rows caused by the forward movement of the sensor. Therefore the sensitivity of a TDI with \( n \) rows is \( n \) times that of an imager using the pushbroom principle.

Incoming light or radiation from the surface is split by beam splitters into the wavelength ranges specified by the instrument. By means of a set of lenses, the incoming photons are projected onto the array containing light-sensitive elements on which the charge accumulating is proportional to the integrated light intensity. For signal read-out, the charges accumulated on the detector elements are passed through an amplifier and digitizer for analog to digital conversion. This results in a digital signal, referred to here as raw radiance, digitized in 8, 12 or 16 bit. Detector materials currently used are silicon for the 0.4–1.0-\( \mu \)m, lead sulfide for the 0.8–2.5-\( \mu \)m, and indium antimonide for the 0.8–5.0-\( \mu \)m range. Spectral separation into the channels needed can be done through a dispersion element (grating/prism) or a filter-based system. Dispersion elements collect spectral images by using a grating or a prism. The incoming EM radiation will be separated into distinct angles. The spectrum of a single ground pixel will be dispersed and focused at different locations of one dimension of the detector array. This technique is used for both whiskbroom and pushbroom image-acquisition modes. HSIs use mainly gratings as the dispersive element. A narrow band of a spectrum can be selected by applying optical bandpass filters (tunable filters, discrete filters, and linear wedge filters). A linear wedge filter functions by transmitting light at a center wavelength that depends on the spatial position of the illumination in the spectral dimension. The detector behind the device receives light from different wavelengths of the scene.

Spectral response is not homogenous when measured over the area covered by a pixel. The point spread function (PSF) describes the decline of the measured signal and is found using a monochromator covering the sensor designated wavelength coverage and different pinhole targets.

For each spectral channel that the sensor acquires, the radiance is variable. Rather than a channel sensing only photons of one particular wavelength, the channel measures radiance in a wavelength range that stretches from a few nanometers lower to a few nanometers higher wavelength than the center wavelength of the channel. The curve describing the decline of the radiance levels around the central channel wavelength for each channel is known as the SRF (Figure 7) which can again be deduced from monochromator measurements.

Imaging spectrometers take indirect measurements of physical parameters in the sense that the digitized signal recorded is directly proportional to the incoming photon energy but not measured in any physically meaningful unit. The relation between the raw digitized signal and a meaningful physical parameter is established after radiometric correction yielding spectral radiance measured as the photon flux power per unit solid angle per wavelength interval. During radiometric calibration the radiometric response function is derived from the relation between the signal, caused on the detectors by the bombardment by photoelectrons, and the incoming radiance. This function translates raw radiance into spectral radiance. The function is measured by mounting the sensor onto a so-called IS, which is a half sphere reference surface coated with highly reflective barium sulfate and isolated from daylight. A set of lamps produce light of known spectral radiance in the IS which can be compared with the measurements of the sensor. These are cross-calibrated using a field spectroradiometer with a known standard. The radiometric response function corrected for the spectral response and geometric response as well for the temporal response (not further elaborated here) gives the at-sensor spectral radiance. Since the radiometric response function is linear it can be represented by two coefficients, the gain and offset, \( c_1 \) and \( c_0 \), respectively for each channel. Calculation of the at-sensor radiance, \( L \), from raw recorded digital signal, \( DN \), using given gain and offset values is done by Equation (17)

\[
L = c_0 + c_1 \times xDN = \text{mW cm}^{-2} \text{sr}^{-1} \mu\text{m}^{-1} \tag{17}
\]

Often thermal sensors are calibratable using two on-board blackbodies (bb), one with a low temperature, \( T_{bb1} \), the other with a high temperature, \( T_{bb2} \). Calculation of these two temperatures is done by Equation (18)
and a second with a high temperature $T_{bb2}$. The at-sensor radiance $L_{bb}$ can now be found from Equation (18) as

$$L_{bb} = L_1(T_{bb1}) + \frac{L_2(T_{bb2}) - L_1(T_{bb1})}{D_{bb2} - D_{bb1}}(DN - D_{bb1})$$

(18)

where $D_{bb1}$ and $D_{bb2}$ are the digital numbers (DNs) for blackbody 1 and 2 and $L_1(T_{bb1})$ and $L_2(T_{bb2})$ are the corresponding spectral radiances for blackbody 1 and 2.

Most instruments measure physical parameters indirectly by generating and recording a signal, that is a DN, which is related to this physical parameter, that is radiance. The empirical relationship between the raw signal and the desired physical parameter is done through instrument calibration. The radiometric response function defines the relation between the signal caused by $N_{\text{ph}}$ and the incoming spectral radiance, $L_{\lambda}$. Thus each image channel needs to be calibrated to derive its radiometric response function which translates raw signal into (at-sensor) spectral radiance through a linear relationship. $N_{\text{ph}}$ is not only a function of the incident spectral radiance but is also related to sensor characteristics of which the SRF and the PSF are the two most important. Image channels are generally defined with an upper and lower wavelength defining the portion of the EM spectrum for which they are sensitive. However, what actually is sensed in terms of the wavelength range of the EM spectrum and its contribution to the total signal is represented by the SRF, recording the relative contribution to the signal of a channel of each wavelength portion of the EM spectrum. Similarly the PSF defines the aerial sensitivity of the instrument. Recall that spectral radiance is an integration over area.

Given the effects of atmospheric attenuation and sensor characteristics, remotely sensed data need to be properly calibrated to derive radiance or reflectance at sensor or at the surface. Absolute radiance or reflectance calibration can be achieved through the use of RT models that model an ideal atmosphere. Relative measurements can be derived by applying calibration coefficients provided by the instrument manufacturers. These coefficients allow translation of the given raw DN to at-sensor radiance and reflectance and are usually the result of an experiment in an IS, that is a pure reflecting environment in which sets of lamps allow radiation to be created with known radiance levels which are in turn measured by the sensor. The relation between the radiance levels and the sensor registered digital values provides an empirical coefficient for the correction. Conversion from the raw digital values to at-sensor spectral radiances is accomplished with Equation (19)

$$L_{\lambda} = \text{Gain} \times DN + \text{Bias}$$

(19)

### 5.3 Spatial Preprocessing Chain

Aircraft data suffer from spatial distortions related to the carrier movements and the ruggedness of the terrain. Modern aircraft remote sensing campaigns are flown with on-board global positioning systems (GPSs) for absolute location of the aircraft at acquisition time and with on-board gyrots that record tilt of the aircraft in terms of roll, pitch, and yaw. In geometric correction, for each pixel the original observation geometry is reconstructed based on the flight line, aircraft altitude, surface topography, and aircraft navigational information. The result of the correction is geocoded sensor radiance data. Geometric distortion of AIS data resulting from data recording can be characterized through four effects (Figure 8; Rothfuss(77)):

1. **Panoramic effect:** owing to the scanning with constant angular scanning speed, pixels become larger from nadir to the left- and right-hand sides of the scan line.
2. **Over- and undersampling:** owing to nonperfect synchrony between air-speed, altitude, and scan speed in the flight direction, redundant information is scanned or data holes occur.
3. **Geometric distortions due to projection:** owing to movements of the aircraft, roll, pitch, and/or yaw distortions may occur.
4. **Drift effect:** owing to side wind or other effects the airplane may become off course and as a result distortions occur in the flight path.

In addition, topographic effects (1) result in shift of pixel locations compared with the true position and (2) affect the pixel size. In order to allow a geocoding of AIS data, on-board gyroscopic measurements record the attitude of the aircraft in terms of roll, pitch, and yaw and differential GPS measurements record the flight path in $x$, $y$, and $z$-absolute coordinates. This information can be used for geocoding of the image data. Three approaches can be applied:

![Figure 8](image-url)

**Figure 8** Common geometric distortions found in AIS data. (Reproduced by permission of DLR from H. Rothfuss, *VDI Verlag* (1994).\(^{(77)}\))
1. geocoding using control points and registration to a map base;
2. geocoding using pixel transformations through gyroscope data;
3. parametric geocoding using gyroscope data, flight line information, and a digital terrain model.

The first approach is commonly used in remote sensing and assumes planar correlation between a number of ground control points that are characterized in the image as well as on a map to which the image data has to be transformed. Geocoding using registration to a map base using classical control point registration methods with \( n \)-term polynomial or rubber sheeting image warping techniques has not been applied very successfully. With satellite data such transformations are commonly used with success. However in the case of airborne data with complex nonplanar distortions, results are typically less accurate. An example of geocoding using gyroscope data is found in Clark et al.\(^{78}\) Here pixel transformations using on-board navigation and engineering data are used to obtain geocoded imaging spectrometer data. These authors demonstrate that for AVIRIS absolute geocoding to accuracies less than 100 m nominal can be achieved. The most advanced geocoding is parametric geocoding\(^{74}\) for which airplane position and attitude (i.e. navigation data, \( x, y, z \) coordinate from a differential global positioning system (DGPS) and engineering data, roll, pitch, and yaw or true heading) as well as a digital elevation model (DEM) (with same coordinate system as the airplane, accuracy about the pixel size of the image data) are needed. Geocoding proceeds in four steps:

1. calculating the current observation geometry, i.e. the effective and ideal pixel-location vector from airplane position and attitude;
2. finding the intersection point to the surface, i.e. creating an oversampled DEM with accuracy better than the nominal pixel size and calculating test-vectors on the DEM to obtain the corresponding pixel vector;
3. obtaining the four corner points of each pixel, i.e. calculating effective vectors for each corner, and obtaining the DEM coordinates;
4. resampling to the original DEM geometry.

This approach, dependent on data characteristics and accuracy/resolution of the DEM, allows positional accuracies in the order of tens of meters to be achieved for AVIRIS data.

5.4 Noise Adjustment

Signal in imaging spectrometry is considered to be the quantity measured by an imaging spectrometer sensor, whereas noise describes the random variability of the signal. The quantification of the noise level alone is not a very useful measure of the quality of the imaging spectrometer data set, since the effect is more severe when the signal is low. Therefore, in most studies the signal-to-noise ratio is used as an estimate of the ratio of the signal’s mean to its standard deviation. Imaging spectrometer data sets contain both periodic (coherent) sensor noise that can be removed and random noise that cannot. The signal-to-noise calculation is done on data sets with periodic noise removed. The remaining random noise can be additive noise, which is independent of the signal, and multiplicative noise which is proportional to the signal. The major part of the noise in imaging spectrometer data sets is additive and decreases sharply with both an increase in wavelength and atmospheric absorption. This random noise component consists of random sensor noise (which is image-independent), intrapixel variability (resulting from spatially heterogeneous pixel contents), and interpixel variability.

An increase in signal-to-noise ratio can be obtained by reducing the noise and retaining the signal. A method for doing this is the maximum noise fraction (MNF) transform developed by Green et al.\(^{79}\) The MNF algorithm is a method for ordering data cubes into components of image quality using a cascaded principal components transform that selects new components in order of decreasing signal-to-noise ratio. In this approach, the gray levels are considered to be linear combinations of an uncorrelated signal component and a correlated noise component in which the gray level covariance is the sum of the signal and the noise covariance matrices. The difficulty in applying the MNF technique lies in finding these covariance matrices. The gray level covariance matrix can be readily derived as the sample covariance matrix of the data, but the noise covariance matrix is more complex to assess. Green et al.\(^{79}\) showed that estimating the noise covariance matrix is unnecessary when noise occurs in one band only. These authors developed a procedure known as minimum/maximum autocorrelation factors (MAF) to estimate the noise covariance matrix for more complex cases. MAF exploits the fact that in most remote sensing data the signal at any pixel is strongly correlated with the signal at neighboring pixels, while the noise is not. The original data are transformed into linear orthogonal combinations in order of increasing spatial correlation which can be subsequently treated. The common approach is to apply low-pass filtering to the low-order MAF factor images which contain most of the low spatially correlated noise and a degraded signal component and removal of the high-MAF factor images that contain almost only noise. After filtering, the cleaned MAF factor images are backtransformed to the original data space. In Figure 9, the first, tenth, twentieth, and
The optical properties of the atmosphere have been described in section 5.2 as well as the underlying basic assumptions of the physics of remote sensing. Interaction of photons with constituents of the atmosphere take the form of scattering by particles (aerosol, dust, etc.) or molecules (gases) and absorption. The combined effect of absorption and scattering is known as extinction. Radiation reaching the sensor can be split into four components: path radiance, reflected diffuse radiance, reflected direct radiance and reflected radiance from the neighborhood. RT codes model the atmosphere’s optical behavior given user-defined boundary conditions. The inverse problem of atmospheric correction of imaging spectrometers to reflectance by correcting for atmospheric influence thus shifting all spectra to nearly the same albedo. The result is a data set in which each pixel can be represented by a reflectance spectrum that can be compared to data acquired either in the field or in the laboratory. Reflectance data obtained can be absolute radiant energy or apparent reflectance relative to a certain standard in the scene. Comparative analysis of several methods for radiance to reflectance correction of imaging spectrometer data can be found in Rast et al., Roberts et al., and Van der Meer. Calibration to reflectance can be conducted to result in absolute or relative reflectance data. An example of a bright and dark target spectrum before and after atmospheric correction is shown in Figure 11.

spectrometer data with the aim of obtaining radiance and/or reflectance at the ground surface can be achieved in three ways:

1. empirical correction methods to obtain apparent surface reflectance;
2. use of RT codes to obtain absolute reflectance;
3. in-flight calibration of airborne optical sensors.

It should be noted that empirical approaches such as those listed above only approximate the highly variable processes in time and space in the atmosphere controlling the transfer of radiance to and from the Earth’s surface to the sensor.

### 6.2 Relative Reflectance

In relative reflectance data, reflectivity is measured relative to a standard target from the scene. Correction methods currently available for this purpose include:

- flat-field correction
- internal average relative reflectance (IARR) correction, and
- empirical line (EL) correction.

The purpose of the flat-field correction is to reduce the atmospheric influence in the raw imaging spectrometer data and eliminate the solar irradiance drop-off, as well as any residual instrument effects. This is achieved by dividing the whole data set by the mean value of an area within the scene which is spectrally and morphologically flat and spectrally homogeneous. The flat-field chosen should have a high albedo to avoid decreasing the signal-to-noise ratio. This can also be achieved by increasing the number of pixel spectra used to produce the flat-field spectrum. In order to select a flat-field target area properly, ground truth data are necessary to ensure that the calibration target is indeed spectrally flat. In this case, the flat-field method removes the solar irradiance curve and major gaseous absorption features as well as system-induced defects.

The IARR correction method,\(^8\) allows the calibration of raw imaging spectrometer data to reflectance data when no calibration information is available. This procedure uses an “average reference spectrum” (ARS) calculated as the average pixel spectrum of the entire scene. This spectrum is divided into each image radiance spectrum to produce a relative reflectance spectrum for each pixel. Care should be taken when cover types with strong absorption features are present in the scene. In such a case the IARR correction method may cause artefacts which may be wrongly interpreted as being spectral features.

Conversion of raw imaging spectrometer data to reflectance data using the EL method\(^8\) requires the selection and spectral characterization of two calibration targets,\(^8\), thus assuming a priori knowledge of each site. This empirical correction uses a constant gain and offset for each band to force a best fit between sets of field spectra and image spectra characterizing the same ground areas, thus removing atmospheric effects, residual instrument artefacts, and viewing geometry effects. The correction requires four basic steps:\(^8\)

1. The first step is the choice of two ground target regions with a wide albedo range (e.g. a dark and a bright target) and acquiring field spectra characterizing these targets.
2. Next, multiple pixels are selected that are associated with each of the two ground targets.
3. Then, an over-determined system of linear equations may be constructed for each band in which the number of unknowns is two, the gain and offset values, and the number of knowns is equal to the total number of image pixels chosen. Solving these equations by means of least-squares fitting provides gain and offset spectra and a standard error for these values for each parameter at each wavelength. The gain spectrum is an inverse solar irradiance curve, whereas the offset spectrum is a negative correction factor that increases with wavelength.
4. The final step, the actual calibration of the data, is a multiplication of the instrument DN values by the proper gain factor adding a corresponding offset value.
6.3 Absolute Reflectance

Absolute reflectance data without a priori knowledge of surface characteristics can be obtained using atmosphere models. These models correct for scattering and absorption in the atmosphere due to water vapor and mixed gases as well as for topographic effects and different illumination conditions. The 0.94-µm and 1.1-µm water absorption bands are used to calculate water vapor in the atmosphere while transmission spectra of the mixed gases in the 0.4–2.5-µm wavelength region are simulated on the basis of the water vapor values found and the solar and observational geometry. Scattering effects in the atmosphere are modeled using RT codes. A typical atmospheric correction algorithm using RT codes typically models the atmosphere’s behavior under incident radiation through deriving transmission spectra of the main atmospheric gases and water vapor which are integrated with the effects of atmospheric scattering from aerosols and molecules. User input on the atmospheric condition required is the date, time, and location of data take, ozone depth, aerosol type, visibility, and elevation. This is derived from radiosonde data or meteorological stations in the area to be imaged. RT codes often used are low-resolution transmittance (LOWTRAN) code, moderate-resolution transmittance (MODTRAN) code, 5S (simulation of the satellite signal in the solar spectrum) and 6S (second simulation of the satellite in the solar spectrum). An example of an atmospheric correction algorithm using RT codes to derive surface reflectance data for DAIS and AVIRIS can be found in Richter and Gao et al., respectively. For a recent discussion on RT codes consult Richter91 or Zagolski and Gastellu-Etchegorry.94

In general, in atmospheric correction the reflective (VIS/SWIR) and thermal spectral regions are treated separately since the influence of the sun dominates the solar reflective region while it can be neglected in the thermal region. The basic relation defining spectral radiance in the VIS/SWIR region is given by Equation (20)

\[ L_\lambda = L_0(\lambda) + \frac{E_g(\lambda)}{\pi} [\tau_{\text{dir}}(\lambda) + \tau_{\text{diff}}(\lambda)] \rho(\lambda) \]  

(20)

where \( L_0(\lambda) \) is the path radiance for a blackbody (\( \rho = 0 \)), \( E_g(\lambda) \) is the global irradiance on the ground, \( \tau_{\text{dir}}(\lambda) \) is the direct atmospheric transmittance (ground to sensor), \( \tau_{\text{diff}}(\lambda) \) is the diffuse atmospheric transmittance (ground to sensor), and \( \rho(\lambda) \) is the reflectance of a Lambert surface. The basic relation defining spectral radiance in the thermal region is given by Equation (21)

\[ L_\lambda = [\varepsilon_\lambda L_{\text{bb},\lambda}(T) + (1 - \varepsilon_\lambda) L_{\text{sky},\lambda}] T_\lambda + L_{\text{atm},\lambda} \]  

(21)

where \( L_\lambda \) is the spectral radiance for the wavelength \( \lambda \), \( \varepsilon_\lambda \) is the surface emissivity at wavelength \( \lambda \), \( L_{\text{bb},\lambda}(T) \) is spectral radiance from a blackbody at surface temperature \( T \), \( L_{\text{sky},\lambda} \) is spectral radiance incident upon the surface from the atmosphere, \( \tau_\lambda \) is spectral atmospheric transmission, and \( L_{\text{atm},\lambda} \) is the spectral radiance from atmospheric emission and scattering that reaches the sensor. Atmospheric values in these equations are typically simulated using RT codes in conjunction with radiosonde data to derive wavelength-dependent surface emissivity (TIR) or reflectance (VIS/SWIR).

For a spaceborne sensor, the following relation can be demonstrated to relate ground reflectance, \( \rho \), to the DN value, Equation (22)

\[ \rho = \frac{1}{a_1} \frac{\pi(c_0 + c_1)DN}{E_s \cos \Theta_s} - a_0 \]  

(22)

where \( E_s \) is the extraterrestrial solar irradiance, \( \Theta_s \) is the solar zenith angle, and \( a_0 \) and \( a_1 \) are atmospheric functions relating planetary albedo, \( \rho_p \) to ground albedo, \( \rho \), in Equation (23) as

\[ \rho_p = a_0 + a_1 x \rho \]  

(23)

For airborne sensors the term \( E_s \cos \Theta_s \) has to be replaced by \( E_g \) the global downwelling flux at the sensor altitude. The adjacency effect is approximately taken into account by calculating an \( N \times N \) pixel low-pass filter image \( \bar{\rho}^{(1)} \) of the reflectance data \( \rho^{(1)} \) and by weighting the difference of \( \rho^{(1)} - \bar{\rho}^{(1)} \) for each pixel with a correction function \( q \) to obtain the corrected reflectance values \( \bar{\rho}^{(1)} \) in Equation (24) as

\[ \rho^{(2)} = \rho^{(1)} + q(\rho^{(1)} - \bar{\rho}^{(1)}) \]  

(24)

where \( q \) is a function of the strength of the adjacency effect depending on the diffuse transmittance (ground to sensor) which results in the scattering of radiation of neighboring fields onto the FOV (see also Richter93).

6.4 In-flight Calibration

In-flight calibration of imaging spectrometers has a dual purpose: validating the laboratory calibration of the instrument and absolute calibration of the instrument. As laboratory calibration yields coefficients to convert raw data (DNs) to a physical quantity (at-sensor radiance) it cannot be assumed that these calibration coefficients also apply to the airborne environment. Therefore, in-flight calibration is an additional method of obtaining calibration coefficients and monitoring the instrument’s radiometric stability over a flight season. For most instruments, in-flight calibration is performed at the beginning and end of the flight season. A homogenous bright area on the ground is selected as target. AVIRIS
is often calibrated over a playa near Rogers Dry Lake, CA, USA, and DAIS is calibrated at the La Grau test site\(^{(98)}\) in France which is also used for calibration of the SPOT satellite. Ancillary information measured during the calibration flight is generally surface reflectance, atmospheric optical depths, and atmospheric water vapor, aerosols (size distribution function, spectral optical thickness), atmospheric gas transmission from passive optical measurements at ground level, and radiosonde data. These in situ measurements are used to constrain a RT code predicting spectral radiances incident onto the instruments aperture resampled to its SRF. Predicted and measured radiances can be evaluated to derive radiometric calibration coefficients for each channel as well as their radiometric accuracy. Based on the calibration coefficients and the specified atmospheric data, reflectance data are obtained. Details on in-flight calibration are found in Green\(^{(70)}\) and Slater et al.\(^{(97)}\).

7 THEMATIC ANALYSIS TECHNIQUES FOR ABSORPTION FEATURE EXTRACTION

7.1 Overview

Once reflectance-like imaging spectrometer data is obtained, the logical next step is to map absorption features to determine surface composition. “Conventional” remote sensing techniques such as band depth mapping using ratios or differences or visual inspection of image spectra can be applied. These often provide useful information and visualizations of the data, but need experience in interpretation. Algorithms used here are restricted to those developed specifically to make use of or cope with the high spectral dimensionality typical for imaging spectrometer data. Such techniques include:

- binary encoding
- waveform characterization
- spectral feature fitting (SFF)
- spectral angle mapping (SAM)
- spectral unmixing
- constrained energy minimization (CEM)
- classification, and
- cross-correlogram spectral matching (CCSM).

7.2 Binary Encoding

A simple binary code for a reflectance spectrum can be described by Equation (25) as\(^{(99)}\)

\[
\begin{align*}
    h(n) &= 0 & \text{if } x(n) \leq T \\
    &= 1 & \text{if } T < x(n)
\end{align*}
\]  

(25)

where \(x(n)\) is the brightness value of a pixel in the \(n\)th channel, \(T\) is the user-specified threshold which often equals the average brightness value of the spectrum, and \(h(n)\) is the resulting binary code for the pixel in the \(n\)th band.

A variation of this simple encoding is to break the spectral range into a number of subregions and to code separately within these subregions following the same procedure as described above. A modification of the simple encoding has been proposed by Jia and Richards\(^{(98)}\) who exploit multiple thresholds. Their method consists of determining the mean brightness of a pixel vector and then additionally setting upper and lower thresholds. The binary code in two-bit format can now take four different values, Equation (26)

\[
\begin{align*}
    h(n) &= 00 & \text{if } x(n) \leq T_1 \\
    &= 01 & \text{if } T_1 < x(n) \leq T_2 \\
    &= 10 & \text{if } T_2 < x(n) \leq T_3 \\
    &= 11 & \text{if } T_3 < x(n)
\end{align*}
\]  

(26)

where \(T_1\) is the lower threshold, \(T_2\) is the mean brightness of the spectrum, and \(T_3\) is the higher threshold.

Binary encoding provides a simple mean of analyzing data sets for the presence of absorption features. However, with the simple 0–1 coding much depends on the threshold chosen. Comparison of 0–1 coded pixel and laboratory spectra yields a qualitative indication of the presence or absence of absorption features where the depth, and thus the significance of the absorption feature, is not considered.

7.3 Waveform Characterization

In waveform characterization\(^{(99)}\) first the imaging spectrometer data are normalized to produce reflectance-type images. The upper convex hull is calculated as an enveloping curve on the pixel spectra which have no absorption features. Next, the hull-quotient reflectance spectrum is derived by taking the ratio between the pixel reflectance features. Hull quotient spectra are used to characterize absorption features, known to be attributed to a certain mineral of interest, in terms of their position, depth, width, asymmetry, and slope of the upper convex hull.\(^{(100)}\) These hull quotient spectra are used to characterize absorption features, known to be attributed to a certain mineral of interest, in terms of their position, depth, width, asymmetry, and slope of the upper convex hull.

The absorption band position, \(\lambda\), is defined as the band having the minimum reflectance value over the wavelength range of the absorption feature. The relative depth, \(D\), of the absorption feature is defined as the reflectance value at the shoulders minus the reflectance value at the absorption band minimum. The width of the
absorption feature, $W$, is given by Equation (27)

$$ W = \frac{A_{\text{all}}}{2D} $$

(27)

where $A_{\text{all}}$ is the sum of the area left of the absorption band minimum, $A_{\text{left}}$, and the area right of the absorption band minimum, $A_{\text{right}}$, forming the total area under the convex hull enclosing the absorption feature. The symmetry factor, $S$, of the absorption feature is defined by Equation (28) as

$$ S = 2 \left( \frac{A_{\text{left}}}{A_{\text{all}}} - 1 \right) $$

(28)

where $A_{\text{left}}$ is again the area of the absorption from starting point to maximum point. Values for $S$ range from $-1.0$ to $1.0$ where $S$ equals $0$ for a symmetric absorption feature. The slope of the upper hull, $\phi$, characterizes the slope of the upper hull over the absorption feature and is defined by Equation (29) as

$$ \phi = \tan^{-1} \left( \frac{R_e - R_s}{\lambda_e - \lambda_s} \right) $$

(29)

where $R_e$ and $R_s$ are the reflectances at the ending and starting point of the absorption feature, respectively, and $\lambda_e$ and $\lambda_s$ are the wavelengths at the ending and starting point of the absorption feature, respectively.

As a result of the waveform characterization, five images (e.g. a position, depth, width, symmetry, and slope of upper hull image for each absorption feature selected) can be generated defining the similarity between a pixel spectrum and a laboratory spectrum of a mineral of interest based on the presence of characteristic absorption features in both spectra. However, Okada and Iwashita \(^{99}\) give no solution to the mineral mapping from these images. Techniques need to be developed to estimate the probability of a mineral occurrence quantitatively from the waveform characteristics.

Data normalization using a single internally derived reference spectrum can result in spectral curves that are distorted from those observed in true reflectance spectra. To avoid this problem, Crowley et al. \(^{103}\) developed a method of mineral mapping from an imaging spectrometer using relative absorption band-depth images (RBD) generated directly from radiance data. In essence, RBD images provide a local continuum correction \(^{102}\) removing any small channel-to-channel radiometric offsets, as well as variable atmospheric absorption and solar irradiance drop-off for each pixel in the data set. To produce a RBD image, several data channels from both absorption band shoulders are summed and then divided by the sum of several channels from the absorption band minimum. The resulting absorption band-depth image gives the depth of an absorption feature relative to the local continuum which can be used to identify pixels having stronger absorption bands indicating that these may represent a certain mineral.

### 7.4 Spectral Feature Fitting

SFF, also known as the TRICORDER algorithm, \(^{101,103,104}\) builds on waveform characterization in that it is a absorption feature-based method for matching image to laboratory spectra. Again continuum removed pixel spectra are used and compared to continuum reference spectra of known mineralogy (possibly derived from a spectral library). A least-squares fit is calculated band by band between each reference end member and the unknown pixel spectra. The root mean square (RMS) error of this fit is used to create an RMS image that shows pixels that are more and pixels that are less similar to the selected reference end member (see Figure 12).

### 7.5 Spectral Angle Mapping

SAM \(^{105}\) calculates the spectral similarity between a test reflectance spectrum and a reference reflectance spectrum.

![Figure 12](image-url) Spectral similarity image (a) and RMS image (b) from SFF for the mineral alunite using 1995 AVIRIS data from Cuprite, Nevada.
assuming that the data are correctly calibrated to apparent reflectance with dark current and path radiance removed. The spectral similarity between the test (or pixel) spectrum, \( t \), and the reference (or laboratory) spectrum, \( r \), is expressed in terms of the average angle, \( \Theta \), between the two spectra as calculated for each channel, \( i \), in Equation (30) as

\[
\Theta = \cos^{-1} \left( \frac{\sum_{i=1}^{n} t_i r_i}{\sum_{i=1}^{n} t_i^2 \sum_{i=1}^{n} r_i^2} \right)
\]

In this approach, the spectra are treated as vectors in a space with dimensionality equal to the number of bands, \( n \). The outcome of the SAM for each pixel is an angular difference measured in radians ranging from zero to \( \pi/2 \), which gives a qualitative estimate of the presence of absorption features that can be related to mineralogy (Figure 13).

7.6 Spectral Unmixing

The most widely used method for extracting surface information from remotely sensed images is image classification. With this technique, despite the stochastic concept of the method, each pixel is assigned to one of several known categories or classes through a statistical separation approach. Thus an image is decomposed into an image containing only thematic information of the classes previously selected as the expected image elements. In general, a training sample set of pixels is defined by the user to train the classifier. The spectral characteristics of each training set are defined through a statistical or probabilistic process from feature spaces, and unknown pixels to be classified are statistically “compared” with the known classes and assigned to the class to which they mostly resemble. In this way thematic information is obtained disregarding the mostly compositional nature of surface materials. Reflected radiation from a pixel as observed in remote sensing imagery has rarely interacted with a volume composed of a single homogenous material because natural surfaces composed of a single uniform material do not exist in nature. Most often the EM radiation observed as pixel reflectance values results from the spectral mixture of a number of ground spectral classes present at the surface sensed. Singer and McCord\textsuperscript{106} showed that if the mixing scale is macroscopic such that photons interact with one material rather than with several materials, the mixing can be considered

\( \text{Figure 13} \) Spectral angle maps for (a) alunite, (b) kaolinite, (c) calcite and (d) silica using 1995 AVIRIS data from Cuprite, Nevada. Gray levels indicated the spectral angle in radians (note that brighter pixels are less similar).
linear and the resulting pixel reflectance spectrum is the linear summation of the individual material reflectance functions multiplied by the surface fraction they constitute. Various sources contribute to spectral mixing: (1) optical imaging systems integrate reflected light from each pixel, (2) all materials present in the FOV contribute to the mixed reflectance sensed at a pixel, and (3) variable illumination conditions due to topographic effects result in spectrally mixed signals. Mixing can be considered a linear process if: (1) no interaction between materials occurs, each photon seeing only one material, (2) if the scale of mixing is very large as opposed to the size of the materials, and (3) if multiple scattering does not occur.

Rather than aiming to represent the landscape in terms of a number of fixed classes, mixture modeling and spectral unmixing acknowledge the compositional nature of natural surfaces and strive to find the relative or absolute fractions (or abundance) of a number of spectral components or end-members that together contribute to the observed reflectance of the image. Therefore the outcome of such analysis is a new set of images that for each selected end-member portray the fraction of this class within the volume bound by the pixel. Mixture modeling is the forward process of deriving mixed signals from pure end-member spectra, while spectral unmixing aims to do the reverse, deriving the fractions of the pure end-members from the mixed pixel signal. A review of mixture modeling and spectral unmixing approaches can be found in Ichoku and Karnieli.

Mixture modeling aims to find the mixed reflectance from a set of pure end-member spectra. This is based on work by Hapke and Johnson et al. on the analysis of RT in particulate media at different albedos and reflectances by converting reflectance spectra to single-scattering albedo. Mustard and Pieters derived the following expression relating bidirectional reflectance $R(i, e)$ defined as the radiant power received per unit area per solid angle viewed from a specific direction $e = \cos^{-1} \mu$ and a surface illuminated from a certain direction $i = \cos^{-1} \mu_o$ by collimated light to the mean single-scattering albedo $W$ in Equation (31) as

$$R(i, e) = \left\{ \frac{W}{4(1 + \mu_o)} \right\} [H(\mu)H(\mu_o)]$$

where $e$ is the viewing angle, $\mu_o = \cos(i)$, $\mu = \sin(e)$ and $H(\mu)$ is a function describing multiple scattering between particles that can be approximated by Equation (32)

$$H(\mu) = \frac{1 + 2\mu}{1 + 2\mu(1 - W)^{0.5}}$$

The mean single-scattering albedo of a mixture is a linear combination of the single-scattering albedos of the end-member components weighted by their relative fraction in Equation (33) as

$$W(\lambda) = \sum_{j=1}^{n} W_j(\lambda)F_j$$

where $W$ is the mean single-scattering albedo, $\lambda$ is the spectral waveband, $n$ is the number of end-members and $F_j$ is the relative fraction of component $j$. $F_j$ is a function of the mass fraction $M_j$, the density, $\rho$, and the diameter $d_j$ of the end-member $j$ in Equation (34) as

$$F_j = \frac{M_j/\rho d_j}{\sum_{j=1}^{n} M_j/\rho d_j}$$

Thus these equations allow us to model reflectance properties and mean single-scattering albedos of mixtures and form the basis of mixture-modeling studies. Spectral unmixing is a deconvolution technique that aims to estimate the surface fractions of a number of spectral components (or end-members) together causing the observed mixed spectral signature of the pixel. A linear combination of spectral end-members is chosen to decompose the mixed reflectance spectrum of each pixel, $R_i$, into fractions $f_j$ of its end-members, $R_{ij}$, by Equation (35)

$$R_i = \sum_{j=1}^{n} f_j R_{ij} + \varepsilon_i \quad 0 \leq \sum_{j=1}^{n} f_j \leq 1$$

where $R_i$ is the reflectance of the mixed spectrum in image band $i$ for each pixel, $f_j$ is the fraction of each end-member $j$ calculated band by band, $R_{ij}$ is the reflectance of the end-member spectrum $j$ in band $i$, $i$ is the band number, $j$ is each of the $n$ image end-members and $\varepsilon_i$ is the residual error or the difference between the measured and modeled $DN$ in band $i$. A unique solution is found from this equation by minimizing the residual error, $\varepsilon_i$, in a least-squares solution. This residual error, $\varepsilon_i$, is the difference between the measured and modeled $DN$ in each band and should in theory be equal to the instrument noise in the case where only the selected end-members are present in a pixel. Residuals over all bands for each pixel in the image can be averaged to give a RMS error, portrayed as an image, which is calculated from the difference of the modeled ($R_{jk}$) and measured ($R'_{jk}$) pixel spectrum in Equation (36) as

$$RMS = \sqrt{\frac{1}{m} \sum_{k=1}^{m} \frac{(R_{jk} - R'_{jk})^2}{n}}$$

where $m$ is the number of end-members and $n$ is the number of image end-members and $\varepsilon_i$ is the residual error or the difference between the measured and modeled $DN$ in band $i$. A unique solution is found from this equation by minimizing the residual error, $\varepsilon_i$, in a least-squares solution. This residual error, $\varepsilon_i$, is the difference between the measured and modeled $DN$ in each band and should in theory be equal to the instrument noise in the case where only the selected end-members are present in a pixel. Residuals over all bands for each pixel in the image can be averaged to give a RMS error, portrayed as an image, which is calculated from the difference of the modeled ($R_{jk}$) and measured ($R'_{jk}$) pixel spectrum in Equation (36) as
where \( n \) is the number of spectral bands and \( m \) the number of pixels within the image. The solution to the unmixing is found through standard matrix inversion such as the gaussian elimination method. Boardman\(^{112} \) however, suggested the use of singular value decomposition of the end-member matrix which has the advantage that singular values can be evaluated to determine the orthogonality of the selected end-members. If all end-members are spectrally unique, all singular values are equal. For a degenerate set of end-members all but one singular value will be zero.

A solution to the mixing as found by a process of matrix inversion is give by Settle and Drake.\(^{113} \) These authors define a vector of expected pixel signals \( \mu_i = [\mu_{i1}, \mu_{i2}, \ldots, \mu_{in}]^T \) for the \( n \) ground-cover classes giving an expected mixed pixel signal under strictly linear conditions in Equation (37) as

\[
f_1\mu_1 + f_2\mu_2 + \cdots + f_c\mu_c = Mf
\]

The columns of the matrix \( M \) are the vectors \( \mu_i \) which are the end-member spectra. The observed signal of pure pixels will exhibit statistical fluctuations due to sensor noise characterized by a noise variance–covariance matrix \( N \). Therefore pixels with the mixture \( f \) will exhibit fluctuations around their mean value \( Mf \) characterized by the noise covariance matrix \( N(f) \) given by Equation (38)

\[
N(f) = f_1N_1 + f_2N_2 + \cdots + f_cN_c
\]

If the \( N(f) \) is independent of \( f \), thus when the noise components are uncorrelated, the linear model can be defined according to Settle and Drake\(^{113} \) in Equation (39) as

\[
x = Mf + e
\]

where \( e \) is the vector of errors satisfying Equation (40)

\[
E(e) = 0 \quad \text{and} \quad E(e^Te) = N
\]

This signifies that the expectation of \( e \) is zero and that the expectation of the noise component is close to the sensor noise component.

The spectral unmixing model requires a number of spectrally pure end-members to be defined which cannot exceed the number of image bands minus one in order to allow a unique solution to be found that minimizes the noise or error of the model. Furthermore, constraining factors arise where fractions sum to unity and fractions for the individual end-members vary from 0 to 100%. Constrained unmixing makes the assumptions stated above. Other cases of unmixing not taking into account these assumptions are referred to as unconstrained unmixing.

Two versions of spectral unmixing are generally implemented: constrained and unconstrained unmixing. Constraining assumptions that can be implemented separately are (1) that the fractions are non-negative and (2) that the fractions sum to unity. These constraints are only meaningful when considering the scientific field of applications (e.g. the earth science perspective). From a statistical viewpoint, or even from an image interpretation viewpoint, it is meaningless to force mixture models to be constrained to the data. The set of end-members should describe all spectral variability for all pixels, produce unique results, and be of significance to the underlying science objectives. Selection of end-members can be achieved in two ways:

1. selecting end-members from a spectral (field or laboratory) library; and
2. deriving end-members from the purest pixels in the image.

The second method has the advantage that selected end-members were collected under similar atmospheric conditions. The end-members resulting from application of the first option are generally denoted as “known” end-members while the second option results in “derived” end-members. Identification of the purest pixels in the scene is done through compression of the data using principal component analysis (PCA) following a method developed by Smith et al.\(^{114} \) Spectrally pure pixels are found at the vertices of the polygon that bounds the data space of the principal components. Selection of spectral end-members often is an iterative process where additional end-members are selected on the basis of clearly visible spatial patterns in the RMS error image until the RMS error obtained does not show any obvious systematic spatial patterns of error distribution. Boardman et al.\(^{115} \) introduced an algorithm for finding the most spectrally pure pixels using the pixel purity index (PPI). The PPI is computed by an iterative process of projecting \( n \)-dimensional scatterplots (where \( n \) is the number of bands) onto a random unit vector and recording the number of times that each pixel is marked as extreme. An example of the results obtained through spectral unmixing of AVIRIS data from Cuprite are shown in Figure 14.

### 7.7 Constrained Energy Minimization

CEM developed by Farrand and Harsanyi\(^{116} \) is an extension to spectral unmixing. CEM maximizes on a pixel-by-pixel basis the response of a target signature and suppresses the response of undesired background signatures. It is assumed that foreground and background signatures are mixed linearly, as is the case when each photon only interacts with one material. The CEM strives at finding a vector that suppresses the unknown background signature while enhancing the
target signature. This is achieved by minimizing the total output energy of all pixels and by assuming the energy of an individual pixel summed across the wavelength range to be one when applied to the target pixel spectrum. The result of CEM is a vector component image that is comparable to fraction abundance images typically obtained through unmixing.

7.8 Classification

Classification of remotely sensed imagery into groups of pixels having similar spectral reflectance characteristics is often an integral part of digital image analysis. On the basis of the spectral reflectance that training pixels (e.g. pixels known to represent a ground class of interest) exhibit, pixels for which the ground cover type is unknown are classified. Classification routines aim to compare the observed spectral reflectance of pixels with unknown composition with that of training pixels, and assign the unknown pixel to that group which most resembles their spectral reflectance characteristics. Techniques making use of training data sets are referred to as supervised classification algorithms as opposed to unsupervised classification techniques in which no foreknowledge of the existence of ground classes is required. Supervised and unsupervised image classification techniques have been widely used in the analysis of conventional remote sensing data type (e.g. Landsat MSS and TM, and SPOT) and several studies have been undertaken to develop algorithms based on classification.

Figure 14 Abundance (fraction) images for (a) calcite, (b) kaolinite, (c) illite/muscovite, and (d) buddingtonite for 1995 AVIRIS data from Cuprite, Nevada. The resulting RMS image is shown (e) together with the PPI (f) image used for end-member selection.
for hyperspectral data types. Cetin et al.\(^{117}\) and Cetin and Levandowski\(^{118}\) use \(n\)-dimensional probability density functions (PDFs) based on the principle of the maximum likelihood classifier to analyze AVIRIS, Thermal Infrared Multispectral Scanner (TIMS), and Landsat TM images. Lee and Landgrebe\(^{119}\) give algorithms for the minimum distance classifier in high-spectral-resolution imagery. An approach using neural networks is given in Benediktsson.\(^{120}\) An alternative classification algorithm for imaging spectrometer data based on indicator kriging is given in Van der Meer.\(^{121,122}\)

### 7.9 Cross-correlogram Spectral Matching

CCSM\(^{123,124}\) is a new approach toward mineral mapping from imaging spectrometer data using the cross-correlogram of pixel and reference spectra. A cross-correlogram is constructed by calculating the cross-correlation at different match positions, \(m\), between a test spectrum (i.e. a pixel spectrum) and a reference spectrum (i.e. a laboratory mineral spectrum or a pixel spectrum known to represent a mineral of interest) by shifting the reference spectrum over subsequent channel positions by Equation (41):

\[
\begin{equation}
    r_m = \frac{\sum_{i} \lambda_i \lambda_t}{\sqrt{\sum_{i} \lambda_i^2} \sqrt{\sum_{i} \lambda_t^2}}
\end{equation}
\]

(41)

where \(r_m\) is the cross-correlation at match position \(m\), \(\lambda_t\) is the test spectrum, \(\lambda_r\) is the reference spectrum, \(n\) is the number of overlapping positions (spectral bands), and \(m\) the match position. The statistical significance of the cross-correlation coefficient can be assessed by a Student’s \(t\)-test and the skewness can be calculated as an estimation of the goodness-of-fit. The cross-correlogram for a perfectly matching reference and test spectrum is a parabola around the central matching number (\(m = 0\)) with a peak correlation of one. Deviations from this shape indicate a different surface mineralogy. Mineral mapping on a pixel-by-pixel basis is achieved by extracting three parameters from the cross-correlograms and combining these into a statistical estimate of the goodness-of-fit of the two spectra compared: the correlation coefficient at match position zero, the moment of skewness (based on the correlation differences between match numbers of equal but reversed signs, e.g. \(m = 4\) and \(m = -4\)), and the significance (based on a Student’s \(t\)-test testing the validity of the correlation coefficient at \(m = 0\)). In order to evaluate the surface mineralogy maps a RMS error assessment procedure is proposed in Van der Meer and Bakker\(^{125}\) in which the error is calculated from the difference between the calculated pixel cross-correlogram and the ideal cross-correlogram calculated for the reference in Equation (42) as (Figure 15):

\[
    RMS = \sqrt{\frac{\sum_{0}^{M} (R_M - R'_M)^2}{N}}
\]

(42)

where \(R_M\) is the pixel cross-correlation at match position \(m\), \(R'_M\) is the reference cross-correlation at match position \(m\), \(N\) is the number of match positions, \(M\) is the match number.

### 8 EXTRACTING EMISSIVITY FROM THERMAL INFRARED DATA

Thermal radiance measured from the Earth’s surface in the TIR region consists of temperature and emissivity information. Variations in emissivity relate to the chemistry and texture of materials at the surface. However, these are blurred by the effects of temperature variations which are an order of magnitude larger that the emissivity effects. Planck’s function (defined earlier) relates surface temperature of a perfect blackbody to spectral radiance. Most surface materials do not emit radiance like a perfect blackbody, their spectral emissivity \((\varepsilon_{ij})\) is defined as the ratio of the radiance of the material to that of a blackbody at the same temperature given in Equations (43) and (44) as

\[
    \varepsilon_{ij} = \frac{L_{ij}}{L_{ij}^{bb}}
\]

(43)

or

\[
    L_{ij} = \varepsilon_{ij}L_{ij}^{bb}
\]

(44)

where \(L_{ij}\) is the radiance of the material and \(L_{ij}^{bb}\) the radiance of a blackbody of similar temperature. From this it can be seen that, if radiance is measured from the surface in \(n\) channels, there will always be \(n + 1\) unknowns, \(n\) emissivities (one per channel) and an unknown surface temperature. Assumptions are needed to solve these equations, and several methods were proposed to find emissivities and temperature. A common approach is the thermal log residuals (see Hook et al.\(^{126}\)) approach that utilizes Wien’s approximation of Planck’s law, Equation (45)

\[
    L_{ij}^{bb} = \frac{C_1}{\lambda_i^2 \pi (e^{C_2/\lambda_i} - 1)}
\]

(45)

where \(C_1\) and \(C_2\) are the first and second radiation constants. Taking natural logs of the surface radiance
Figure 15 Surface mineralogy map for alunite (a) at Cuprite, Nevada and corresponding RMS (b) from 1995 AVIRIS data.

using Wien’s approximation we obtain Equation (46)

\[ \ln L_{ij} = \ln \varepsilon_{ij} + \ln C_1 - 5 \ln \lambda_j - \ln \pi - \frac{C_2}{\lambda_j T_i} \]  \hspace{1cm} (46)

This relation is manipulated with a set of means derived from the data in order to obtain the thermal log residual value consisting only of the emissivity term in Equation (47) by

\[ Y_{ij} = X_{ij} - X_i - X_j + X_s \]  \hspace{1cm} (47)

where \( X_{ij} \) is the wavelength-weighted log of the Wien radiance at pixel \( i \) in channel \( j \) in Equation (48) equal to

\[ X_{ij} = \lambda_j \ln \varepsilon_{ij} + \lambda_j \ln C_1 - 5 \lambda_j \ln \lambda_j - \lambda_j \ln \pi - \frac{C_2}{T_i} \]  \hspace{1cm} (48)

\( X_s \) is the geometric mean over all channels for pixel \( j \) in Equation (49) equal to

\[ X_s = \frac{1}{n} \sum_{j=1}^{n} \lambda_j \ln \varepsilon_{ij} + \frac{\ln C_1}{n} \sum_{j=1}^{n} \lambda_j - \frac{n-1}{n} \sum_{j=1}^{n} \lambda_j \ln \lambda_j - \frac{C_2}{T_1} \]  \hspace{1cm} (49)

with \( n \) as the number of channels.

\( X_i \) is the geometric mean over all pixels in the scene for channel \( i \) in Equation (50)

\[ X_i = \frac{\lambda_j}{N} \sum_{j=1}^{N} \ln \varepsilon_{ij} + \frac{\lambda_j \ln C_1}{n} \sum_{j=1}^{n} \lambda_j - \frac{n-1}{n} \sum_{j=1}^{n} \lambda_j \ln \lambda_j \]  \hspace{1cm} (50)

where \( N \) is the number of pixels in a channel.

\( X_s \) is the geometric mean over all pixels in all channels given by Equation (51)

\[ = \frac{1}{nN} \sum_{i=1}^{N} \sum_{j=1}^{n} \lambda_j \ln \varepsilon_{ij} + \frac{\ln C_1}{n} \sum_{j=1}^{n} \lambda_j - \frac{n-1}{n} \sum_{j=1}^{n} \lambda_j \ln \lambda_j \]  \hspace{1cm} (51)

Now the residual value is found in Equation (52) as

\[ Y_{ij} = \lambda_j \ln \varepsilon_{ij} - \frac{1}{n} \sum_{j=1}^{n} \lambda_j \ln \varepsilon_{ij} - \frac{\lambda_j}{N} \sum_{i=1}^{N} \ln \varepsilon_{ij} \]  \hspace{1cm} (52)
If $l_i = \lambda_i/\lambda_*$ and $e_{ij} = (\varepsilon_{ij})^l$ where $\lambda_*$ is the mean of the central wavelengths of all channels then Equation (53) follows

$$Y_{ij} = \frac{\ln e_{ij} - \frac{1}{n} \sum_{j=1}^{n} \ln e_{ij} - \frac{1}{N} \sum_{i=1}^{N} \ln e_{ij}}{\ln e_{ij} - \frac{1}{N} \sum_{i=1}^{N} \ln e_{ij}} + \frac{1}{nN} \sum_{j=1}^{n} \sum_{i=1}^{N} \ln e_{ij}$$

Thus the thermal log residuals represent variations in a combination of emissivities for a given channel rather than variations of temperature and emissivity.

9 APPLICATIONS OF IMAGING SPECTROMETRY

9.1 Overview

In this section, applications of imaging spectrometry are discussed. Technological studies on sensor performance, calibration and validation of sensor characteristics as well as studies that evaluate new processing strategies are not elaborated. Earth-science-related applications, especially geological studies, are emphasized. Most of the studies are discussed in a rudimentary fashion; the interested reader is referred to the references for further details.

9.2 Mineral Mapping: Surface Mineralogy

Goetz et al.\(^\text{14}\) demonstrated that spectroscopy may aid in surface mineralogy mapping. This early work was the start of a large number of similar types of work. Murphy\(^\text{127}\) for the first time succeeded in mapping jasperoid in the Cedar mountains. An expert system approach without a priori knowledge of the area was successfully implemented by Dwyer et al.\(^\text{128}\) where they applied AVIRIS data to surface mineralogy mapping in the Drum mountains of Utah (USA). Similarly, Gaddis et al.\(^\text{129}\) presented techniques that use only information contained within a raw AVIRIS data set to estimate and remove additive components (atmospheric scattering and instrument dark current), normalize multiplicative components (instrument gain, atmospheric transmission), and enhance, extract, and map surface composition and mineralogy. Kruse et al.\(^\text{130}\) presented mineral mapping using an expert-systems approach. Ben-Dor et al.\(^\text{131}\) and Ben-Dor and Kruse\(^\text{132}\) demonstrated that mineral maps (derived using spectral unmixing techniques) from GER 63-channel imaging spectrometer data over the Makhtesh Ramon area in Israel provide additional geological details not yet revealed on existing geological maps. This work builds on earlier studies by Kaufman et al.\(^\text{133}\) and Crowley et al.\(^\text{103}\) using AIS data (AVIRIS) of the Ruby mountains, Montana for mineral discrimination using RBD images. Crowley\(^\text{134}\) also presented a study on mapping of evaporite minerals with AVIRIS in Death Valley. A study by Farrand and Seelos\(^\text{135}\) showed the possibility of mapping faults by evaluating mineral maps for linear or curvilinear features. These authors were able to delineate some previously unmapped faults in the Summitville area from mineral end-member images obtained using the CEM technique. The use of classification methods including neural networks for mapping surface mineralogy from AVIRIS data of a volcanic terrain on Iceland is described in Benediktsson\(^\text{120}\) Baugh et al.\(^\text{136}\) showed the potential of AVIRIS for mapping ammonium-type minerals.

9.3 Mineral Mapping: Exploration

Numerous studies on remote sensing to aid in mineral exploration have been conducted at Cuprite and Goldfield, Nevada (USA), two of NASA's test sites for instrument calibration and geological mapping. Most of these studies center on mapping of hydrothermal alteration to aid in mineral prospecting (particularly for gold). Calibration and testing of new sensors as well as validating new processing strategies is typically conducted at Cuprite. Cuprite and Goldfield are areas of extensive hydrothermal alteration within a sequence of rhyolitic welded ash flow and air fall tuffs\(^\text{17,18}\) which can be subdivided into three mappable units: silicified rocks, opalized rocks, and argillized rocks. Silicified rocks form a large irregular patch extending from the middle to the south end of the area. The silicified core represents the most intensely altered rocks at Cuprite containing quartz, calcite, and minor alunite and kaolinite. Opalized rocks contain abundant opal and as much as 30% alunite and kaolinite. Locally, an interval of soft poorly exposed material mapped as argillized rock separates fresh rock from opalized rock. In the argillized rocks, plagioclase is altered to kaolinite, and glass is altered to opal and varying amounts of montmorillonite and kaolinite. The distribution of these alteration assemblages is characteristic of a fossilized hot-spring deposit, which often contains gold.

Volcanism at Cuprite began in Oligocene with eruption of rhyolite and quartz latite flows. Hydrothermal alteration is related to a second, early Miocene, period during which dacite and andesite flows were extruded and hot acidic brines began circulating through the volcanics. The general geology of the Cuprite mining district is treated in more detail in Abrams et al.\(^\text{139}\) Mineral zones can be mapped as rings around a central vent formed by altered silica. The alteration zones are composed of kaolinite, alunite, buddingtonite, and various ferrigenous minerals.
characterizing the host rocks. Some of the sedimentary units show mappable amounts of calcite and dolomite. The mineral zonation is indicative of a sulfuric acid-charged system with hydrothermal fluids emitted in a hot spring-type of environment. The circular distribution of the mineral zones demonstrates that alteration occurred along a central vent with the lateral mineral zoning controlled by a decrease of acidity and temperature. It should be noted that alunite is a pathfinder mineral for gold; in fact for many years gold has been explored at mines near the town of Goldfield.

Some examples of recent studies at Cuprite (Figure 16) and Goldfield (data and (in some cases) the analytical technique given in parentheses) include those of Resmini et al.\textsuperscript{140} (HYDICE, CEM), Okada and Iwashita\textsuperscript{99} (waveform characterization), Abrams and Hook\textsuperscript{141} (simulated ASTER data, decorrelation stretching), Nedeljkovic and Pendock\textsuperscript{150} (AVIRIS, PDFs), Carrere and Abrams\textsuperscript{143} (AVIRIS), Kruse et al.\textsuperscript{88} (GER 63-channel imaging spectrometer), Hook et al.\textsuperscript{144} (AVIRIS, Geological Scanner Geoscan), Van der Meer and Bakker\textsuperscript{124} (AVIRIS, CCSM).

Other examples of gold mineral exploration through mapping of hydrothermal alteration zones are described by Crosta et al.\textsuperscript{145} who use Geoscan AMSS MK-II data in an area in the Rio Itapicuru greenstone belt in the northeastern part of Brazil, Ferrier and Wadge\textsuperscript{146} who use AVIRIS data from southern Spain, Hutsinipple\textsuperscript{147} who used AIS-I data from Virginia City (Nevada), Feldman and Taranik\textsuperscript{148} who used AIS-I data to map alteration minerals in the Tybo mining district (Nevada), and Crosta et al.\textsuperscript{149} who use AVIRIS data for alteration mapping at Bodie (California).

Other alteration processes that have been studied in imaging spectrometer data are the serpentinization of ultramafic rocks which relates to major asbestos deposits. Based on the laboratory studies of Hunt and Evarts\textsuperscript{150} it has been shown that the degree of serpentinization of ultramafic rocks can be estimated through spectral analysis of imaging spectrometer data.\textsuperscript{151} Beratan et al.\textsuperscript{152}

![Figure 16 Cuprite, Nevada as seen from AVIRIS. (a) Image cube (face is a red, green, blue image with $R = 2.2$, $G = 2.3$, $B = 2.4 \mu m$) where the sides of the cube are formed by spectral slices through the (in this example) 40 image channels that form the SWIR part of the spectrum. Color coding is in terms of reflectance (red is high, black is low reflectance), each line represents one channel. (b) Surface mineralogy showing kaolinite in yellow, alunite in cyan, silica in red, and buddingtonite in dark blue. (c) Field photographs of the area showing Joshua trees with rhyolite in the background. (d) Field photograph showing large deposits of white alunite in the front and hills consisting of kaolinite in the middle.](image-url)
used AVIRIS to map potassium metasomatism, a type of alteration marked by addition of large amounts of potassium at the expense of sodium. These authors mapped hematite as a proxy for potassium since potassium itself has no distinct absorption features to be evaluated. Van der Meer et al.\cite{153} used data from the Chinese MAIS to map surface mineralogy in the Jinchuan ultramafic intrusion. This work contributed to prospecting for nickel–copper sulfide mineralizations in the Gansu province of China. Another case of hydrothermal alteration mapping in rhyolites and acid volcanics is presented in Loercher et al.\cite{154} who studied the Torfajokull volcanic complex of Iceland using AVIRIS and map zonation patterns related to active geothermal fields. Mapping of mineral-bound ammonium (buddingtonite) in hydrothermally altered rocks to permit the determination of fluid chemistry in fossil hot springs was demonstrated by Baugh and Kruse\cite{155} for the southern Cedar mountains using AVIRIS data.

9.4 Mineral Mapping: Lithology

An example of remote mineralogic and lithologic mapping using AVIRIS is presented for the Ice River Alkaline complex of British Columbia (Canada) by Bowers and Rowan.\cite{156} These authors use spectral unmixing techniques to map mineralogy related to shales, slates and limestones incorporating vegetation and weathering products into the analysis. Integration of optical, thermal and radio detection and ranging (RADAR) data from AVIRIS, TIMS, and airborne synthetic aperture RADAR (AIRSAR) by Keirin-Young\cite{157} shows the synergy of such an approach while mapping surface geology and morphology in alluvial fans in the Death Valley area (California, USA). Alternatively, geological imaging spectrometry may be used to assist metamorphic facies mapping for regional geological investigations (e.g. Rowan et al.\cite{158}, Van der Meer\cite{159}). Through the analysis of the position of the absorption band in the 2.3 μm wavelength range it has been shown that mapping calcite versus dolomite is possible from imaging spectrometer data thus allowing us to map dolomitization patterns from space.\cite{160,161} This has potential for petroleum exploration since porosity increase due to dolomitization makes these rocks potential reservoir rocks. Mustard\cite{162} used the relationship between soil, grass, and bedrock to map in a serpentinite melange using AVIRIS data. A last example comes from Lang and Cabral-Canoz\cite{163} who use AVIRIS data for tectonostratigraphic mapping in the Northern Guerrero state of southern Mexico.

9.5 Vegetation Stress and Geobotany

Indirect detection of mineral deposits using imaging spectrometer data has been attempted through analysis of spectra of “stressed vegetation”. Collins et al.\cite{164} were the first to report the shift of the red edge (e.g. the point of maximum slope on the reflectance spectrum of vegetation between red and NIR wavelengths) toward the blue end of the spectrum as a result of stress due to copper in the subsurface. These authors claimed that the position and shape of the red edge could be used as a guide in mineral prospecting. Their work has led to a still ongoing debate on the potential use of the red-edge shift. Although the amount and direction of shift as a result of geochemical stress on vegetation is uncertain, most workers agree that the red edge can be used to assess the vitality of plant communities (see, for example, Boochs et al.\cite{165} for a discussion on this topic). Work on the use of vegetation stress indicators derived from AVIRIS data can be found in Clark et al.\cite{156} and Ebeling et al.\cite{167}. An overview of techniques for delineating the red edge can be found in Dawson and Curran.\cite{168}

9.6 Environmental Geology

High-spectral-resolution data of the Geoscanner Mk II were used to delineate mercury-contaminated mill tailings within an Environmental Protection Agency (EPA) Superfund site in north central Nevada where surface geochemical data could be used for validation of the results.\cite{169} Similarly, Lehmann et al.\cite{170} investigated GER spectra of a vegetation-covered mine waste deposit. Farrand and Harsanyi\cite{171} map the distribution of mine tailings in the Coeur d’Alene River valley, Idaho, through their CEM Technique. Farrand\cite{171} used AVIRIS data to map pernicious trace metals, ferric oxides, and oxyhydroxide minerals in an acid water environment. The trace metals are released into the environment as a result of mining operations. Traditionally, such phases are mapped in the field using geochemical sampling and laboratory analysis. Bianchi et al.\cite{172} used data from the MIVIS to map oil spills over land by relating the parts per million of oil with the oil hyperspectral information gathered by the imaging sensor. Their study focuses on the oil spilled during the blow-out from an Agenzia Generale Italiana Petroli (AGIP) rig located within the Ticino Regional park in Italy. Mapping of abundance images of goethite, jarosite, hematite, kaolinite, muscovite, montmorillonite along with vegetation and soil from AVIRIS over the Leadville area of Colorado aided in an environmental hazard assessment while muscovite/illite mostly corresponded to mine tailings and iron minerals often were associated with dark smelter slag materials.\cite{173} The combination of airborne Daedalus-ATM (Airborne Thematic Mapper) scanner data and imaging spectrometer (reflective and thermal) data from DAIS was used to map the area of a former uranium mining site in eastern Germany.\cite{174} Mapping of temperature anomalies and
differentiation of surface materials allowed assessment of the hydrologic conditions at the site and provided information relevant for recultivation. In a paper by Clark et al., a US Geological Survey (USGS) initiative is outlined for monitoring of superficial geology, vegetation communities, and environmental materials in the US National Parks to aid in ecosystems environmental mapping.

9.7 Petroleum-related Studies

Bammel and Birnie studied the spectral reflectance response of big sagebrush to hydrocarbon-induced vegetation stress in the Bighorn basin of Wyoming and found a significant blue shift (to shorter wavelengths) of the green reflectance peak at 0.56 μm and a red trough (0.67 μm) as stress indicators. However, these authors concluded that the correlation found between geobotanical anomalies in relation to surface or subsurface hydrocarbons could not be demonstrated with statistical significance. Yang et al. surveyed two profiles in an oil-rich basin in the delta of the Yellow river in China. Field spectral measurements of monocultural winter wheat over areas known to have light hydrocarbon gas seepages constrained from subsurface gas measurements showed an anomalous red shift (contrary to the result of Bammel and Birnie) of the red edge of the vegetation spectrum. Although a visual relationship between gas measurements and spectral anomalies could be seen, no statistical significant correlation could be demonstrated. Mapping of dolomitization patterns through mapping dolomite versus calcite concentration is a goal of remote sensing since dolomites have a 12% greater porosity than limestones containing calcite, thus making them interesting host rocks for oil accumulation.

Winder and Lyon demonstrated the possibility of separating calcite from dolomite in GeoScan airborne data although their study centered on mineral prospecting in skarn-type deposits. In a series of publications, Van der Meer demonstrated that imaging the shift of the carbonate absorption would allow mapping of compositional variations in dolomite and calcite percentages. Hydrocarbon soil geochemistry and airborne spectrometer data were integrated with Landsat TM imagery for a portion of the Sao Francisco basin of Central Brazil by De Oliveira and Crosta. This approach allowed these authors to map both soil and vegetation anomalies related to hydrocarbon microseepages.

9.8 Atmospheric Effects Resulting from Geological Processes

Most studies use imaging spectrometer data calibrated to reflectance. As discussed previously, raw imaging spectrometer radiance data show absorption features that can be attributed to atmospheric gases. In contrast, these absorption features can be used to map quantities and differences in these gases in the atmospheric column. Using ratios of absorption band depth estimates of water bands at 0.95 μm and 1.15 μm, it has been demonstrated that water vapor total column abundance can be mapped from imaging spectrometer data. Similarly, De Jong and Chrien detected abnormally high abundances of carbon dioxide and methane in AVIRIS data from the Mammoth Mountain area which they attributed to renewed volcanic activity.

9.9 Volcanic Hazards

Hydrothermally altered rocks on stratovolcanoes are closely linked to edifice failures and the generation of destructive debris flows while altered rocks form zones of weakness along fractures and contain hydrous clay minerals that modify the physical properties of debris flows. Mapping alteration minerals on the slopes of Mount Rainier using AVIRIS data allowed Crowley and Zimbelman to delineate hazardous sectors and develop a method also applicable to other areas.

9.10 Thermal Infrared Studies

Geological studies using TIR multispectral data date back to the early 1980s when Kahle and Goetz and Kahle derived emissivity information and thermal inertia from the first TIMS data and used it to map mineralogy and some lithologies. Following on from these studies were the first examples that showed that the age of lava flows could be constrained from thermal data. In 1992, Hook et al. presented a comparison of techniques for extracting emissivity information from TIR data for geological studies. Abrams and Hook use the TIMS data to simulate ASTER data and evaluate the use of this data for geological mapping purposes (Figure 17). A comparison of TIR emissivity spectra measured in situ and in the laboratory, and similar spectra derived from NASA’s airborne TIMS in Cuprite (Nevada) using spectral matching techniques, have demonstrated the complementary nature of the thermal region and the reflective region of the EM spectrum. Many silicate minerals that have no diagnostic absorption features in the reflective part of the spectrum and which can therefore be difficult to map using VIS/SWIR spectroscopy show strong features in the thermal part of the spectrum, thus allowing more accurate mapping with thermal spectrometers such as TIMS. TIR spectra of TIMS acquired over sedimentary rocks in the Tarim basin allowed Bihong and Xiaowei to map sandstones, siltstones, argillites, and carbonates accurately using decorrelation stretching. In a decorrelation-stretched color-composite TIMS image, temperature
Figure 17 Linearly stretched (a–c) and decorrelation stretched (d–f) color composites of simulated ASTER data. (a) and (d) display bands 3, 2, and 1 in RGB; (b) and (e) display bands 4, 5, and 9 in RGB; and (c) and (f) display bands 13, 12, and 10 in RGB. The ASTER bands are 1, 0.52–0.60 µm; 2, 0.63–0.69 µm; 3, 0.76–0.86 µm; 4, 1.6–1.7 µm; 5, 2.145–2.185 µm; 9, 2.36–2.43 µm; 10, 8.125–8.475 µm; 12, 8.925–9.275 µm; 13, 10.25–10.95 µm. (Reproduced by permission of IEEE (© 1995, IEEE) from Abrams and Hook, IEEE Trans. Geosci. Remote Sensing.141)
variations show as intensity differences while emissivity differences show as color variations in the image.(193)

ACKNOWLEDGMENTS

The author thanks Dieter Oertel, Peter Strobl and Harald Rothfuss from the Deutsche Forschungsanstalt für Luft- und Raumfahrt e.V. (DLR), Steven de Jong from the University of Utrecht and IEEE for allowing the use of some of their view graphs for illustration. Peter Strobl, Dieter Oertel (DLR), Paul Curran (University of Southampton), Steven de Jong (University of Utrecht) and Harold Lang (NASA Jet Propulsion Laboratory) are thanked for reviewing the manuscript.

IMAGING SPECTROMETRY FOR GEOLOGICAL APPLICATIONS

Land-cover changes are cumulatively transforming land cover at an accelerating pace, mainly in the tropics. These changes in terrestrial ecosystems are closely linked with the issue of the sustainability of socioeconomic development since they affect essential parts of our natural capital such as climate, soils, vegetation, water resources and biodiversity. Changes in terrestrial ecosystems brought about by human activity are driven by land cover conversion, land degradation, land-use intensification or other forms of land cover modification. The term land cover refers to the attributes of a part of the Earth's land surface and immediate subsurface, including biota, soil, topography, surface and groundwater, and human structures. The term land use refers to the purposes for which humans exploit the land cover. One generally distinguishes between land cover conversion, the complete replacement of one cover type by another, and land cover modification, more subtle changes that affect the character of the land cover without changing its overall classification. Land cover modifications are generally more prevalent than land cover conversions. Two types of satellite sensors are used in land cover applications: fine spatial resolution systems and coarse spatial resolution/high temporal frequency systems. Data are collected in the visible, thermal and microwave ranges of the spectrum. Information in the spatial domain also provides valuable information on land surface attributes. These data are analyzed either for land cover mapping or for land cover monitoring. Current research is moving toward the direct estimation of biophysical surface parameters by model inversion methods. Multisensor approaches are also increasingly being developed.

1 INTRODUCTION

1.1 Land Cover and Global Change

Land-use changes are cumulatively transforming land cover at an accelerating pace, mainly in the tropics. These changes in terrestrial ecosystems are closely linked with the issue of the sustainability of socioeconomic development since they affect essential parts of our natural capital such as climate, soils, vegetation, water resources and biodiversity. Actually, changes in land cover have important implications for a range of issues such as biosphere–atmosphere interactions, species and genetic diversity associated with endangered habitats, soil conditions, water and sediment flows and sustainable use of natural resources in the development process of human societies. However, quantitative data on where, when and why such changes take place globally are still incomplete and sometimes inaccurate. Our knowledge and understanding of land...
cover change processes are too fragmented for assessing the broader impact of these changes on natural and human systems. While our knowledge about interactions between land surface processes and climate change has achieved recent advances, there are still a number of unknowns.

Changes in land cover are possibly driven by five categories of causes: long-term natural changes in climatic conditions; geomorphologic and ecological processes (e.g. soil erosion and natural vegetation dynamics); human-induced alterations of vegetation cover and landscapes (e.g. deforestation and land degradation); interannual climatic variability (e.g. recurrent droughts and floods); and human-induced climatic changes. These processes have different impacts on ecosystems and human societies, occur at different rates and scales, and are characterized by varying degrees of reversibility. Because of considerable interactions between these processes, the explanation and prediction of land cover changes is a complex task. The study of land cover change processes requires a three-level approach:

1. direct measurements of the rate, location, spatial pattern and temporal characteristics of land cover changes;
2. case studies and field investigations to gain insights into local-scale dynamics of land cover changes;
3. identification of the broad scale factors that drive land cover changes and allow projection of future trends.

Thus, there is a need both for comparative analyses of the main processes of land cover changes and for advanced methods to monitor and model land cover changes at regional scales. An important research priority is the accurate measurement of land cover change magnitudes and the categorization of change processes. Suitable measurements will allow evaluation of the major driving forces of changes, their potential effects and, eventually, prediction of future trends.

1.2 Major Land Cover Change Processes

Changes in terrestrial ecosystems brought about by human activity are driven by land cover conversion, land degradation, land-use intensification or other forms of land cover modification. The most widespread contemporary example of land cover conversion is tropical deforestation. It is estimated that forest-cover conversion reached an average of 15.5 million hectares per year for the period 1981 through 1990, which translates to an annual deforestation rate of 0.8%. These figures have been critically examined by Grainger. Deforestation is, in most cases, the result of complex causality chains which originate beyond the forestry sector. Forest conversion in the humid tropics accounts for a significant part of the carbon flux from terrestrial ecosystems and contributes to a large share of the loss of biodiversity. Another economically and demographically important process of conversion is urbanization. However, less than 2% of the Earth’s surface can be considered “urban” and only 0.2% is densely built-up.

Land degradation is most severe and widespread in semi-arid regions. It encompasses processes such as soil erosion or soil salinization, which are sometimes described by the controversial concept of “desertification”. Land degradation implies a decline in the usable natural resource base and, thus, directly affects the food supply. It is usually associated with sociopolitical mechanisms leading to a “pressure of production on resources”. A synthesis of the most recent global assessments of human-induced land degradation estimated that 69.5% of the world drylands are affected by various forms of land degradation. However, these assessments were not based on systematic measurement and do not allow derivation of spatially disaggregated rates of desertification. There are strong interactions between dryland degradation, the primary productivity of vegetation and climate.

Land-use intensification may be associated with agricultural, agroforestry or grazing systems. Intensified management of land can be based on such techniques as irrigation, fertilizer use or the integration of different production activities. It may be driven by population pressure, market demand or political economy factors.

1.3 Definitions

1.3.1 Land Cover versus Land Use

The term land cover refers to the attributes of a part of the Earth’s land surface and immediate subsurface, including biota, soil, topography, surface and groundwater, and human structures. Examples of some broad categories of land cover are: boreal forest, tropical savanna, temperate grasslands, croplands, wetlands and settlements. The term land use refers to the purposes for which humans exploit the land cover. Common land uses include agriculture, grazing, forestry, mineral extraction and recreation. Forest is a land cover dominated by woody species, which may be exploited for land uses as varied as recreation, timber production or wildlife conservation. Changes in human land use are frequent causes of land cover conversion and modification. Monitoring land surface processes by remote sensing is directed to changes in biophysical attributes of the surface, i.e. the land cover.
1.3.2 Land Cover Conversion versus Land Cover Modification

One generally distinguishes between land cover conversion, the complete replacement of one cover type by another, and land cover modification, more subtle changes that affect the character of the land cover without changing its overall classification. Land cover modifications may result in degraded ecosystems. Land cover modifications are generally more prevalent than land cover conversions. In principle, the monitoring of land cover conversions (e.g. agricultural expansion or deforestation) can be performed by a simple comparison of successive land cover maps (e.g. derived by classification of remote sensing data or by field surveying). However, the comparison of land cover classifications for different dates does not allow the detection of subtle changes within land cover classes: even if some of the attributes of one class have changed, the magnitude of these changes will not always be large enough to justify a shift from one land cover category to another, unless the vegetation classification identifies a very large number of narrowly defined categories. Therefore, monitoring land cover changes can only be achieved through repetitive measurements of biophysical attributes which characterize the land cover. In this article, remote sensing approaches to measure indicators of the state of land cover and its change are reviewed. The main emphasis of this review is on methods applicable at broad spatial scales.

1.4 Remote Sensing Systems Used

1.4.1 Medium to Fine Spatial Resolution Systems

A number of sensors have acquired multispectral data at a spatial resolution of dozens of meters over several decades. The most widely used among these sensors are: Landsat Multispectral Scanner (MSS) (nominal spatial resolution of 80 by 80 m), Landsat Thematic Mapper (TM) (nominal spatial resolution of 30 by 30 m), and SPOT (Système Probatoire Pour l’Observation de la Terre) High-resolution Visible (HRV) Imaging Instrument (nominal spatial resolution of 20 by 20 m for the multispectral product “XS” and nominal spatial resolution of 10 by 10 m for the panchromatic product). As an example, the spectral bands of the Landsat TM sensor are: 0.45–0.52 μm, 0.52–0.60 μm, 0.63–0.69 μm, 0.76–0.90 μm, 1.55–1.75 μm, 2.08–2.35 μm and 10.40–12.50 μm. Time series of data from these fine spatial resolution sensors can be created to monitor changes in landscapes at a local scale.

A new generation of fine spatial resolution sensors is due to be launched around the turn of the century. These sensors are capable of generating imagery with spatial resolutions as fine as 1 m in panchromatic mode and 4 m in multispectral mode. These systems are also characterized by high geometric precision, short revisit intervals and rapid data supply. However, they have narrow swath widths, which limits data acquisition to relatively small areas. They also have few, broad spectral bands. Such imagery will provide greater spatial detail on the land surface.

1.4.2 Coarse Spatial Resolution/High Temporal Frequency Systems

For some applications, measures of land cover change must be represented at a level of spatial aggregation which matches the spatial resolution of ecosystem models. The potential of coarse spatial resolution (1 km or coarser) remote sensing data with a high frequency of observation (daily) for monitoring changes in the attributes of the Earth’s surface is well documented. Radiation data measured from the Advanced Very High-resolution Radiometer (AVHRR) on the National Oceanic and Atmospherice Administration (NOAA) series of orbiting platforms have been widely used. These data cover the period from June 1981 to present. The daily NOAA AVHRR Local Area Coverage (LAC) data have a spatial resolution of 1.1 km at nadir, which is well suited to monitor seasonal vegetation dynamics at the scale of the landscape. Continental scale, daily Global Area Coverage (GAC) data have a minimum resolution-cell size of 3.3 by 5.5 km and are produced by resampling the 1.1 by 1.1 km spatial resolution data. The spectral bands of the NOAA AVHRR sensor are: 0.58–0.68 μm, 0.72–1.10 μm, 3.55–3.93 μm, 10.30–11.30 μm and 11.50–12.50 μm.

The Along Track Scanning Radiometer (ATSR)-1 sensor embarked on the Earth Resource Satellite (ERS)-1 satellite produced high-quality 1-km spatial resolution data. The sensor collects data in the short-wave infrared (SWIR) part of the spectrum (i.e. reflected energy) and in two thermal infrared channels (i.e. emitted energy). (ATSR-1’s middle infrared channel failed early in the mission.) These data are collected in two 500 km swath looks, one at nadir and the other one some 600 km in front of the platform, at an angle of 55°. Repeat coverage at the equator is between 6 and 9 days, although this will alter depending on the ERS-1 operational cycle. The SWIR channel (ATSR’s channel 1b) overlaps with the Landsat TM channel 5. The thermal channels (ATSR’s channels 2 and 3) overlap with the NOAA AVHRR channels 4 and 5. The ATSR-2 sensor has the same specifications, but with two additional bands in the red and near-infrared (NIR) parts of the spectrum. It has been providing data with two look angles for several years now. The forthcoming ENVISAT (environmental satellite) Mission of European Space Agency (ESA) will include an Advanced Along Track Scanning Radiometer (AATSR) instrument. 
A new promising sensor for land cover monitoring is the Moderate Resolution Imaging Spectroradiometer (MODIS), as part of National Aeronautics and Space Administration (NASA)’s Earth Observing System (EOS). This instrument is similar to the NOAA AVHRR sensor in that it provides frequent temporal coverage of the Earth, acquiring images on a two-day repeat. Unlike NOAA AVHRR, the instrument images in 36 spectral bands from 0.4 to 14 µm selected for studies of atmosphere, ocean and land. The land bands sample regions of the spectrum that are largely similar to those sampled by the Landsat TM, except that bandwidths are much narrower. Spatial resolution of these bands is 500 m, while resolution of two bands in the red and NIR is 250 m. The MODIS instrument will be much better calibrated than AVHRR, and because atmospheric data are acquired simultaneously with land data, it should be possible to routinely correct MODIS land observations for atmospheric effects. A number of MODIS standard land products will be generated, to improve our capability for land surface monitoring at a global scale. MODIS is now scheduled for flight on both morning pass and afternoon pass platforms of EOS, due for launch at the turn of the century.

A sister instrument of MODIS is the Medium Resolution Imaging Spectrometer (MERIS), as part of the forthcoming ENVISAT Mission of ESA. It will include 15 spectral bands in the visible and NIR range, at a 250 m spatial resolution. Both the position and the bandwidths of the spectral bands will be fully programmable by ground command. The data will be fully calibrated on board and corrected for atmospheric effects.

Finally, several active microwave sensors are available: the Synthetic Aperture Radar (SAR) on the ERS-1 and Japanese Earth Resource Satellite (JERS)-1 satellites, and the forthcoming Advanced Synthetic Aperture Radar (ASAR) sensor as part of the forthcoming ENVISAT mission. For all these sensors, a radar beam illuminates the ground and an image of the ground is built up from the return signals, which are dependent on the scattering properties of the individual targets. ERS-1/JERS-1 SAR is a version of side-looking radar, operating in imaging mode, in which high spatial resolution (30 by 30 m for ERS-1, 18 by 18 m for JERS-1) is obtained. The frequency of the radar signal is 5.3 GHz (C-Band) for ERS-1 and 1.25 GHz (L-Band) for JERS-1. Both systems have a single polarization (VV for ERS-1 and HH for JERS-1). The incidence angle of the system in normal operation is 23°. This can be varied up to 35°. ENVISAT ASAR is an advanced active microwave instrument, employing a number of new technological developments.

Note that this enumeration of sensors used for land cover applications is not exhaustive. Only the most commonly used instruments for land applications have been mentioned here.

2 LAND COVER ATTRIBUTES MEASURED BY REMOTE SENSING

2.1 In the Visible Range of the Spectrum

Many authors have characterized the surface using vegetation indices, which are arithmetic combinations of spectral bands. The most widely used of these indices is the normalized difference vegetation index (NDVI). The NDVI is calculated (Equation 1) from reflectances in the red and NIR parts of the electromagnetic spectrum as:

\[
\frac{\text{NIR} - \text{Red}}{\text{NIR} + \text{Red}}
\]

Vegetation indices derived from remote sensing data are related to several variables quantifying vegetation activity and state. Green leaf area index (LAI) is inversely related to red reflectance and positively related to NIR reflectance. Several studies showed that ratio vegetation indices such as the NDVI were related to the fractional vegetation cover of a surface. Empirical studies and simulations with radiative transfer models support the interpretation of the NDVI in terms of fraction of photosynthetically active radiation (PAR) absorbed by the vegetation canopy, canopy attributes (e.g. green biomass or green LAI), state of the vegetation (i.e. vegetation vigor or stress) and instantaneous rates associated with the activity of the vegetation. Seasonal variations of vegetation indices are related to vegetation phenology and biome seasonality. Many other indices have been defined. They are variants of the NDVI and display different levels of insensitivity to perturbing factors such as soil color changes or atmospheric effects.

2.2 In the Thermal Range of the Spectrum

Land surface skin brightness temperature \(T_s\) can be derived (Equation 2) from the thermal channels of the NOAA AVHRR using the split-window technique:

\[
T_s (\text{in degree Celsius}) = T_4 + 3.33(T_4 - T_5) - 273
\]

where \(T_4\) and \(T_5\) are true brightness temperatures in NOAA AVHRR channels 4 and 5 (in degree Kelvin). This formula assumes a constant surface emissivity. The correspondence between the thermal channels of the AVHRR and ATS R sensors means that the split-window algorithm to estimate land surface temperatures \(T_s\) from NOAA AVHRR data can be adapted for use with ATS R data. The ATS R however has a higher
radiometric resolution (12 bit) than the AVHRR (10 bit) for the thermal channels. The potential error magnitude on satellite-derived \( T_s \) is 2–3 \(^\circ\)C.

\( T_s \) is related, through the surface energy balance equation, to surface moisture availability and evaporative transpiration, as a function of latent heat flux.\(^{(40)}\) Empirical studies have demonstrated the usefulness of thermal data to locate dense forest boundaries.\(^{(41)}\) In tropical regions, surface temperature is largely a function of evaporation, when water availability is not limited. Energy is transferred to the atmosphere in the form of latent heat surface temperature is largely a function of evaporation, plant transpiration and direct evaporation of water intercepted by plant canopies. This heat loss determines to a large extent, through the surface energy balance equation, the daily mean temperature of the surface.\(^{(42–44)}\) Main determinants of surface evaporation are radiation, the moisture availability at the surface, the presence of active vegetation, wind speed, surface roughness and atmospheric demand. In the absence of sensible heat advection, net radiation sets an upper limit to the latent heat flux transfer, because of the balance between incoming and outgoing energy fluxes at the Earth’s surface. Evaporative losses of vegetated surfaces also depend on factors such as rooting depth of plants, stomatal resistance, canopy height and structure, soil hydraulic properties, topography and the physiographic and geomorphic characteristics of hydrologic systems. Surface resistance (both aerodynamic diffusion resistance and canopy resistance) is thus influenced by land cover factors such as the amount and type of vegetation and soil characteristics.

2.3 Relationships between Vegetation Indices and Surface Temperature

2.3.1 Biophysical Processes Controlling Surface Temperature and Vegetation Index

Published studies demonstrated the advantage of combining vegetation index (VI) with \( T_s \) data for land cover and land cover change analysis.\(^{(45–47)}\) A negative relationship between remotely sensed vegetation indices and surface brightness temperature has been widely observed.\(^{(48–55)}\) This relationship may be driven by several mechanisms:

1. An increase in green biomass is often associated with a reduction in surface resistance to evapotranspiration, greater transpiration and a larger latent heat transfer. The presence of actively transpiring vegetation thus increases the share of latent heat flux with regard to total available energy. In general, soil water extraction by plant roots occurs more rapidly and at much greater depth than water diffusion to the soil surface. This relationship also depends on the synoptic state of the atmosphere (air temperature and vapor pressure deficit), soil moisture availability and the physiological activity of the vegetation.

2. Radiant surface temperature variations over a vegetated surface result from variations in the proportion of bare soil visible to the radiometer. During daylight hours, plant leaves are cooler than exposed bare soil because the heat capacity of plant leaves is much lower than the heat capacity of soil.\(^{(56)}\) Variations in the proportions of radiances emitted from shaded or unshaded bare soil and vegetation lead to coarse scale variations in apparent aggregated brightness temperature at the level of ground scene elements. The proportions of these scene components within the sensor instantaneous field of view is a function of fractional vegetation cover, canopy three-dimensional architecture, solar elevation angle and viewing geometry. The importance of this effect was demonstrated by Friedl and Davis\(^{(54)}\) over a well-watered tallgrass prairie.

3. The thermal inertia of scene components also influences the \( T_s – VI \) relationship. Thermal inertia measures the thermal response of a material to temperature changes. It is a function of thermal conductivity, thermal capacity and density. It is affected by both permanent surface characteristics (i.e. soil, landform and geological setting) and the transients such as soil moisture, ventilation, vegetative cover or albedo. The thermal inertia of vegetation canopies is lower than the thermal inertia of soils. Mineral constituents of soil have large densities and thermal conductivities compared to foliage, and both mineral constituents and the organic matter in soil have much higher heat capacities than foliage. Moreover, soil moisture has a pronounced effect on soil thermal properties. High soil moisture further increases the thermal inertia of the substrate relative to vegetation canopies. Note that stomatal control of transpiration also influences the diurnal temperature range. Transpiration by plants causes a lower daytime temperature of vegetated surfaces relative to bare soils, and thus has a conflicting effect with the lower thermal inertia of vegetation canopies. The more vegetated a pixel, the more evapotranspiration suppresses the maximum temperature and the smaller the day–night temperature difference. As documented by Whitehead et al.,\(^{(58)}\) this leads to a negative relationship between a VI and the diurnal temperature range, and thus to a negative relationship between a VI and daytime surface temperature.

4. Increasing vegetation height increases surface roughness, until a canopy reaches complete closure. An increase in the roughness of canopies increases turbulent exchange of water above the canopy and the
efficiency of energy dissipation, and thus decreases surface temperature. Even the presence of non-transpiring vegetation could be associated (if other conditions are met) with a lower surface temperature than for bare soil, owing to higher aerodynamic surface roughness. This increase in surface roughness and the resultant decrease in aerodynamic resistance occur to a slight extent for agricultural crops but to a much larger degree for trees, scattered bushes and brush. However, model simulations by Smith and Choudhury\(^{59}\) showed that vegetation height did not significantly affect the \(T_s-\text{NDVI}\) relationship.

5. Over bright soils, a decrease in green vegetation increases surface albedo, which results in reduced surface heating. However, Goward et al.\(^{48}\) showed that this effect is small compared to latent heat exchanges associated with evapotranspiration.

The dominance of one of these processes over the others depends on the land cover type, the climatic and surface moisture conditions and the specific location (e.g. soil type, landform, local climate, spatial heterogeneity in surface attributes, latitude). On surfaces with a low moisture content, latent heat exchanges associated with evapotranspiration seem to be the dominant mechanism accounting for variations in surface temperature with increases in vegetation cover. On well-watered surfaces, it is rather the difference between soil and vegetation thermal properties associated with changes in fractional vegetation cover that drives the \(T_s-\text{NDVI}\) inverse relationship. Spatial variations in surface attributes will cause a negative \(T_s-\text{VI}\) relationship in space. The relationship between \(T_s\) and \(\text{VI}\) brought by seasonal variations in surface attributes depends on environmental conditions. When energy is the main limiting factor to vegetation – e.g. in high-latitude regions – changes in \(\text{VI}\) are positively correlated in time to changes in \(T_s\). This comes from the senescence of vegetation in fall with temperature decreases, followed in spring by vegetation growth with temperature increases. In this case, variations in \(T_s\) control variations in \(\text{VI}\) over the phenological cycle. When water is the main limiting factor to vegetation as is the case in the warm regions of Africa – changes in \(\text{VI}\) are expected to be negatively correlated in time to changes in \(T_s\), for the reasons discussed above.

2.3.2 The Slope of the Surface Temperature and Vegetation Index Relationship

Several authors have attempted to interpret the partial derivative – or the sensitivity – of the \(T_s-\text{NDVI}\) relationship in biophysical terms. Goward et al.\(^{48}\) suggested that the rate of change in surface temperature with changes in the amount of vegetation could be diagnostic of surface resistance to moisture flux. Simulations of water and energy flows in the soil–plant–atmosphere system, using a canopy reflectance model, confirmed that an increase in vegetation amount, as indicated by the \(\text{VI}\), leads to a decrease in the area-averaged minimum canopy resistance and to an increase in latent heat flux. Nemani and Running\(^{50}\) related, over conifer forests, the slope of the \(T_s-\text{NDVI}\) relationship to regional surface resistance due to soil water deficit – i.e. the landscape “dryness”. Smith and Choudhury\(^{59}\) considered a greater variety of land cover types and noted that two separate effects influence the \(T_s-\text{NDVI}\) slope: soil evaporation – the dominant effect for areas with a low NDVI – and leaf stomatal resistance – the dominant effect for areas with a high NDVI. Later, on the basis of broad scale data, Nemani et al.\(^{60}\) concluded that the slope of the \(T_s-\text{NDVI}\) relationship is primarily controlled by fractional vegetation cover, surface moisture status and local meteorological conditions. Over the well-watered surface studied by Friedl and Davis,\(^{54}\) soil background temperature (which is affected by soil moisture) more than surface partitioning of energy into latent versus sensible heat was driving the \(T_s-\text{NDVI}\) relationship. This complicates and reduces the generality of previous interpretations of the \(T_s/\text{NDVI}\) relationship, for instance in terms of surface Bowen ratio conditions.\(^{51}\) Finally, Hope and McDowell\(^{61}\) and Friedl and Davis\(^{54}\) observed that the \(T_s-\text{NDVI}\) relationship depends on land cover type.

In summary, these studies have tended to interpret the partial derivative of the \(T_s-\text{VI}\) relationship only on the basis of one or two of the processes driving it. Simulation studies which would integrate all five processes discussed previously still have to be conducted. Note that the studies reviewed above were performed at a variety of spatial scales: from fine resolution data that can resolve local variations in canopy density, to coarse resolution data that resolve landscape units. In the latter case, the spatially aggregated \(T_s\) and \(\text{VI}\) data are mainly sensitive to continental scale patterns of land use and land cover.

2.3.3 The Surface Temperature and Vegetation Index Space

Previous findings by Price,\(^{52}\) Goward and Hope\(^{51}\) and Nemani et al.\(^{60}\) on the \(T_s-\text{VI}\) feature space are summarized on Figure 1. Over bare soil, variations in radiant surface temperature are highly correlated with variations in surface water content.\(^{62,63}\) Thus, points A and B on Figure 1 represent, respectively, dry bare soil (low VI, high \(T_s\)) and moist bare soil (low VI, low \(T_s\)). As the fractional vegetation cover increases, surface temperature decreases (as seen above, this relationship is driven by several biophysical mechanisms). Point C on Figure 1 corresponds to continuous vegetation canopies
LAND COVER ASSESSMENT AND MONITORING

Figure 1 Surface temperature ($T_s$) and VI space. (Reproduced by permission of Taylor & Francis from E.F. Lambin, D. Ehrlich, Int. J. Remote Sens., 17, 463–487 (1996).)

with a high resistance to evapotranspiration (high VI, relatively high $T_s$) e.g. due to a low soil water availability. Point D corresponds to continuous vegetation canopies with low resistance to evapotranspiration (high VI, low $T_s$) e.g. on well-watered surfaces. The upper envelope of observations in that space, A–C, represents the low-evapotranspiration line (i.e. dry conditions). The lower envelope B–D represents the line of potential evapotranspiration (wet conditions). Recently, Moran et al.\textsuperscript{64} defined a similar “VI/temperature trapezoid” in a space defined by fractional vegetation cover and surface minus air temperatures.

Data values from any scene will be distributed, during the growing season, between these four extreme points of the $T_s$–VI space. Outside the growing season, surfaces in regions which are affected by low air temperatures, i.e. in high latitudes, will have part of their time trajectories outside the area defined by A–B–C–D, with $T_s$ and VI approaching zero in winter. Open bodies of water (and clouds) are characterized by lower VI and $T_s$.

The studies reviewed above led to a good understanding of the biophysical relationships of the $T_s$–VI space. This knowledge can be used to improve current strategies for land cover mapping and change detection, by defining measurements in this feature space. The main issue of land cover mapping is how to partition this space. The main issue of land cover change analysis is how to characterize time trajectories in that space.

2.4 In the Microwave Range of the Spectrum

Information on surface processes is also acquired by sensors that operate in the microwave portion of the electromagnetic spectrum. The cloud-penetrating capability of microwaves makes them an ideal tool to work in areas with a permanent cloud cover (e.g. equatorial regions). Note that microwave reflections and emissions from the land surface are controlled by totally different processes from those that control reflection and emissions in the visible or thermal part of the spectrum. Both active and passive microwave sensing are used. Active systems supply their own source of energy or illumination while passive systems sense energy that is naturally emitted or reflected from the Earth surface, at extremely low levels however. As of today, there have been fewer successful applications of microwave remote sensing for land cover monitoring or mapping than those using optical sensing. There is however a large potential provided that the interpretation of microwave data is approached through a physical modeling approach.

In active systems, the intensity of microwave returning from a given surface depends, on one hand, on the wavelength and polarization of the signal and, on the other hand, on the geometric characteristics of the surface (i.e. shape and orientation of objects, as well as their surface roughness) and its electrical characteristics (i.e. reflectivity and conductivity of materials, as measured by their complex dielectric constant). Note that changes in microwave signal intensity are often related to changes in moisture content more closely than they are to changes in surface materials. In general, green vegetation is a good reflector of microwave energy, because of its high moisture content and large surface area. Also, soil moisture and surface wetness conditions are well detected, particularly with microwave data at long wavelengths. On forest landscapes, the influence of soil moisture variations on the backscattering coefficient in the C-band appears to be the prime cause of dynamic behavior in temporal series of SAR imagery, even when relatively low levels of standing biomass are present.\textsuperscript{65}

The C-band signal tends to saturate with increases in biomass at quite low levels of biomass. Therefore, C-band data are not good for discriminating forests. Even low vegetation canopies can give rise to returns very similar to those from a full forest canopy. The L-band provided by JERS-1 has improved discriminating power of forests as radiation penetrates further into the canopy.\textsuperscript{65} Other authors also found that the L-band was more sensitive to stem volume in a boreal forest than the C-band.\textsuperscript{66,67} The potential of the L-band from JERS-1 to retrieve above-ground biomass density in an equatorial forest was also evaluated as being promising. However, speckle and image texture set a biomass limit at 31 tones per hectare for retrieval purpose.\textsuperscript{68} In general, the C-band is more dependent on weather. Thus, the L-band seems more attractive for biomass estimation.
A recent project has produced a subcontinental scale mosaic of Central Africa based on microwave data, recorded by the ERS-1 SAR sensor. Identification of vegetation types and detection of changes in vegetation cover is most favorable with microwave data on flat to undulating terrain. For example, major success has been reported on the mapping of flooded forest based on ERS-1 and JERS-1 radar data. Mountainous or dissected terrain provides significant difficulties. Combined imagery from the ERS-1 and JERS-1 SAR systems was tested by Kellndorfer et al. for regional-to-global scale vegetation classification. This required high-resolution digital elevation model data for terrain correction of geometric and radiometric distortions. An unsupervised clustering was then applied to the two-dimensional SAR feature space. The combination of orbital L- and C-band SAR data is quite powerful for structural vegetation characterization.

Seasonal contrasts can be exploited on microwave data to discriminate between different cover types (e.g. evergreen versus deciduous formations), given the frequent coverage of the data. Change classes are defined from multitemporal SAR data based on their unique signature of radar backscattering time series. Change classes can then be interpreted in terms of thematic classes, e.g. rice cultivation systems. However, not all time variations in the backscattered microwave signal are of phenological origin.

Image texture analysis on microwave data is also often used for canopy characterization and landscape degradation mapping. The derivation of land surface parameters from microwave data using a model-inversion approach is the subject of continuing research. The problems associated with the extraction of thematic information in complex topography warrant particular attention as, for example, a lot of the tropical forests of the world are located on mountainous terrain. The development of algorithms for exploiting the synergy between optical and microwave data sources is also the focus of current research. Clearly, the all-weather capacity of microwave remote sensing combined with the fine spatial resolution of the data opens promising avenues for land cover assessment and monitoring.

### 2.5 In the Spatial Domain

A major attribute of a landscape is its spatial pattern, i.e. the arrangement in space of its different elements. The concept of landscape spatial pattern covers, for example, the patch size distribution of residual forests, the location of agricultural plots in relation to natural vegetation, the shapes of fields or the number, types and configuration of landscape elements (i.e. their spatial heterogeneity). Landscape spatial pattern is seldom static because of both natural changes in vegetation and human intervention. The spatial dynamics of landscapes interact with ecological processes which have important spatial components, e.g. flows of energy and matter between landscape components, biological productivity, biodiversity, the spread of disturbances.

Remote sensing offers the possibility to analyze changes in spatial structure at the scale of landscapes. Textural information of high spatial resolution remote sensing images is related to biophysical parameters (crown diameter, distance between trees, tree density, tree positioning, LAI, tree height, etc.) and acquisition parameters (spatial resolution, spectral domain and viewing and illumination configurations). Texture can be measured using a variety of indices such as variance, variograms, mathematical morphology or fractals.

Indicators of the degradation of the vegetation cover can be derived from such measures. For example, Pickup and Foran developed a method to monitor arid landscapes used for pastoralism based on the spatial variability of the vegetation. The spatial autocorrelation function and mean-variance plots of a spectral indicator were found to be successful in discriminating between the cover responses typical of good and poor rainfall years. For drought conditions, the decrease in spatial autocorrelation with increasing spatial lag was rapid since the ground surface is bare and most of the vegetation signal comes from scattered areas of trees and shrubs. A low decay rate of the autocorrelation function indicated a greater spatial uniformity of the landscape, e.g. during wet periods when more ground cover is present, reducing the contrast between the bare soil signal and that produced by trees and shrubs. Similar observations were made by Lambin over the seasonal and interannual cycle of three West African landscapes. Vogt also analyzed the seasonal changes in spatial structure of a West African landscape, showing that there is a marked seasonal cycle in the spatial structure of a VI, surface temperature and albedo, and that zones of ecological transition have an identifiable seasonal dynamic in spatial structure. However, the monitoring of these spatial variability measures only provide a qualitative description of the cover state. Hudak and Wessman related a textural index to woody plant densities and woody plant encroachment across savanna landscapes. Actually, heterogeneity in vegetation structure has a significant influence on local pixel variance in high spatial resolution images. These authors found that, in a savanna landscape, woody stem count correlated best with image texture.

Lambin and Strahler showed that the detection by remote sensing of land cover change processes is improved when using both spectral (e.g. VI and surface temperature) and spatial indicators of surface condition. Their study suggested that the detection of interannual
changes in landscape spatial structure is more likely to reveal long-term and long-lasting land cover changes, while spectral indicators are more sensitive to fluctuations in primary productivity associated with the interannual variability in climatic conditions. The long-term monitoring of landscape spatial pattern in addition to other biophysical variables might thus lead to the detection of a greater range of processes of landscape modification. The spatial pattern of a changing landscape also provides some information on the processes of land cover change. Certain categories of changes in human land use tend to fragment the landscape (e.g. expansion of extensive agricultural exploitation, land cover changes driven by small-scale logging, overgrazing or desertification around deep wells). Other land use changes increase landscape homogeneity (e.g. intensive cultivation or ranching over large areas). Spatial processes of gap expansion in a forest cover have been modeled to predict the total gap area and gap size distribution. One can make the hypothesis that landscapes with a low or very high level of disturbance are characterized by a low spatial heterogeneity while landscapes with a medium level of disturbance are very heterogeneous. Recent remote sensing observations grossly supported this hypothesis, e.g. in a study of forest-cover disturbances in Papua New Guinea and another study of forest fragmentation in New England.

Current research investigates the effect of changes in spatial resolution on the image variance, image texture and spatial patterns. The variance of a remotely sensed image is determined by the interaction of scene properties with the spatial characteristics of the sensor, mainly its spatial resolution. Image variance is related to image information content. Texture is caused by the variability or uniformity of image tone or color. The higher the texture, the greater the degree of spatial heterogeneity in the data. Image texture varies with the scale of the data. When texture analysis is applied to images of the same scene with different spatial resolutions, it is argued that the highest texture indicates the resolution level at which most land surface processes operates and, therefore, at which a landscape should be analyzed.

3 DISCRETE VERSUS CONTINUOUS REPRESENTATIONS OF LAND COVER

The land surface can be represented as a set of spatial units which are each associated with an attribute. These attributes are either a single land cover category (i.e. leading to a discrete representation of land cover) or a set of values for continuous biophysical variables (i.e. leading to a continuous representation of land cover). The correspondence between these two representations can be established through a table which associates to each land cover category the average range of values for the biophysical variables.

In the continuous representation of land cover, the biophysical variables vary continuously not only in space but also in time, at the seasonal and interannual scale. By contrast, in the discrete representation of land cover, each spatial unit is represented by a single categorical value which is stable over a season. Interannual changes in the values of the biophysical attributes of the surface are described, in the discrete representation of land cover, as land cover conversions only if the changes exceed the range of values which is characteristic of the land cover category (i.e. if the magnitude of the change is such that the values of all biophysical attributes falls within the range of another land cover class during the entire seasonal cycle). By contrast, a land cover modification, which is not detectable with the discrete representation of land cover, implies that variations in the values of the biophysical attributes remain within the range of values which is characteristic of the land cover category. Processes which lead to changes in the seasonal dynamics or in the fine scale spatial variability of biophysical attributes would also be described as land cover modifications. Changes that would only affect the values of some of the biophysical attributes, for just part of the seasonal cycle would probably also enter in that category. This suggests that monitoring land cover changes by remote sensing requires the measurement of a set of indicators of the biophysical attributes of the surface, the seasonality of these attributes and their fine scale spatial pattern. These information requirements correspond to the three major information sources provided by remote sensing.

4 LAND COVER MAPPING

4.1 Multispectral Approaches

Classification is a method by which labels are attached to pixels in view of their character. This character is generally their spectral response in different spectral ranges. It may also include their spatial attributes (i.e. texture) or temporal signature (see below). This labeling is implemented through pattern recognition procedures, the patterns being pixel vectors. The most commonly used classification methodology is based on the maximum likelihood, a probabilistic classification method which assumes that spectral classes can be described by a normal probability distribution in multispectral space. More advanced classification techniques have been developed recently. Contextual classifiers label a pixel in the context
of its neighbors in space. It exploits spatial information by quantifying the neighborhood relationships of an image. Decision tree classifiers based on a large set of metrics have been used for global land cover mapping. Neural networks are classifier networks, having a decision tree structure, where a collection of simple classifiers is brought together to solve a complex problem. Neural network classifiers have also been proposed for global land cover mapping. A number of studies have demonstrated that neural network-based classification can produce more accurate results than conventional approaches. The reasons include:

1. neural network classifiers are distribution-free and can exploit nonlinear data patterns;
2. neural network classification algorithms can easily accommodate ancillary data;
3. neural network architectures are quite flexible and can be easily modified to optimize performance;
4. neural networks are able to handle multiple subcategories per class.

### 4.2 Multitemporal Approaches

The International Geosphere-Biosphere Programme (IGBP) has endorsed the use of coarse spatial resolution, high temporal frequency imagery for deriving land cover parameters for global change studies. A number of studies have produced broad scale land cover maps from NOAA’s AVHRR. These studies were based on NDVI data time series of one year or less. Rather than analyzing isolated dates, the multitemporal classification approach is based on a comparison of the temporal development curve, or time-trajectory, for different spatial sampling units of indicators derived from NOAA AVHRR data, such as vegetation indices, surface temperature or spatial structure. Various attempts have been made to develop mathematical expressions that fit vegetation development curves, using logistic or exponential expressions. A combination of those for different phases of the radiometric evolution of a vegetative cover, or by jointly using the results of the theories of generalized shift and of projection pursuit. Other studies have used a few simple parameters to characterize the evolution in time of vegetation indices: the onset of greenness, the peak of greenness, the length of growing season, the integrated VI, the amplitude of the variation, etc. Samson proposes a skew index and a range index to characterize the shape of the seasonal profile of vegetation indices. Tucker et al. used the information from the first two principal components of annual NDVI time series as measures of mean annual NDVI value and seasonality to classify the time-profiles of land cover types on a continental scale in Africa. For our objective of comparing successive temporal profiles to detect subtle land cover changes, a method of analysis which captures the maximum detail contained in the time-trajectory of the indicator is needed.

The seasonal dynamic of a remotely sensed indicator can also be represented by a point in a multidimensional space, with the number of dimensions of this space corresponding to the number of observations. These observations will correspond either to the maximum values of the indicator for pre-specified compositing periods, or to the results of a sampling through time of a continuous function that describes the shape of the time-trajectory of the indicator. If we assume monthly-composed data or a monthly rate of sampling, twelve successive images will be available. The value taken by the indicator under consideration can be represented, for each pixel, by a point in the twelve-dimensional temporal space defined by the vector (Equation 3):

\[
p(i, y) = \begin{array}{c} I(t_1) \\
I(t_2) \\
\vdots \\
I(t_n) 
\end{array}
\]  

where \( p(i, y) \) is the multitemporal vector for pixel \( i \) and the year \( y \), \( I \) are the values of the indicator under consideration for pixel \( i \) at the time periods \( t_1 \) to \( t_n \), \( n \) being the number of time dimensions. The magnitude of this vector, \( |p| \), measures the accumulated value of the indicator through the year. The direction of this vector, measured by the direction angles of \( p \), is a synthetic quantifier of the seasonal pattern of the indicator, i.e. the shape of the curve (Lambin and Strahler).

### 4.3 Categorical and Ordinal Legends for Land Cover Maps

Major applications of land cover mapping are the monitoring of land cover changes and the modeling of land cover change processes as well as their climatic, ecological and socio-economic impacts. Land cover mapping is also performed to support land management...
and land-use planning in order to achieve sustainable development. Each of these applications has different requirements in terms of legend, scale and accuracy of the land cover map. For example, for land-use planning, the characteristics of the map should be adapted to the specific needs of the land managers and planners, whether these are rural communities, states or regional institutions. These needs will depend on the main environmental constraints of a specific region and on the socio-economic objectives of the land managers.

Legends of land cover maps are typically at the nominal level: each item of the legend is a specific category, unrelated to the other items. This is the lowest form of measurement, in which the classes differ only in kind, not by degree. For land management, it is useful to upgrade the legend of land cover maps into ordinal levels. In this case, each item of the legend is related to the other items according to an ordinal scale which can be defined on the basis of a variable of interest for land management. For ordinal-level classifications, the classes differ by degree and may be placed in rank order and therefore represents a higher level of measurement than a nominal-level classification. It thus provides a higher level of information to land-use planners and natural-resources managers.

In a few recent studies, noncategorical mapping of land cover were generated by retrieving sub-pixel information on, for example, forest cover percentage using a linear, spectral mixture model, a fuzzy membership function or an empirical calibration function between fine and coarse spatial resolution data. These previous studies derived a continuous variable on forest cover percentage from spectral or spatial information, with no or little indication on forest cover conditions (e.g. degree of disturbance, degradation or heterogeneity of the cover).

### 4.4 Spatial Unmixing of Land Cover Information

The production of broad scale land cover maps generally relies on remote sensing data at a coarse spatial resolution. Thus, complex landscape mosaics are represented by a single value or a single land cover category. As a result, the estimation of land cover proportions from broad scale maps is associated with a systematic bias due to spatial aggregation effects. The magnitude of this error depends on the spatial resolution of the map, the initial proportions of the landscape in the different land covers and the spatial arrangement of the land covers at the fine resolution.

Backward scaling of land cover proportions, which means retrieving the fine scale proportions of land cover classes from the coarse scale data, can be performed through a “double sampling with regression estimator approach”. This method is based on a regression between an “auxiliary” variable, which can be measured over the entire population from coarse resolution data, and the “target” variable (i.e. land cover proportions at a fine resolution). The parameters of this regression are estimated over the sample of fine and coarse resolution data, and then applied over the entire population of coarse resolution data, in order to predict the “true” land cover proportions (i.e. at a fine resolution). This statistical calibration estimator is known as inverse calibration model. It has proved to be more reliable than classical calibration to correct misclassifications in remote sensing.

The double sampling approach for backward scaling can be applied in two ways:

1. by modeling spectral mixtures at the scale of coarse resolution pixels or an empirical calibration model.
2. by modeling the influence of the spatial pattern of land cover classes on the proportional error for blocks of coarse resolution pixels.

In the first approach, referred to as the mixed pixel estimator, a direct relationship between land cover proportions at a fine resolution and the brightness values at a coarse resolution is calibrated over a sample of sites. It does not require classification of the data. The assumptions are that:

- brightness values are stable across space;
- the brightness value at a coarse resolution is mainly determined by the cover proportion of the class of interest;
- the deviations between cover proportions and brightness data are consistent throughout the range of values.

This approach can be implemented using a variety of methods, e.g. linear mixture models, fuzzy classifiers or Bayesian methods.

In the second approach, the land cover proportions at a fine resolution are related to the land cover proportions measured on coarse resolution classifications and the influence of the landscape spatial pattern on this relationship is modeled. Spatial information can either be introduced explicitly as a continuous, exogenous variable in the model or indirectly, through a spatial stratification of the study area based on landscape attributes. When the spatial pattern of the landscape is not included in a correction model, the parameters of the function are specific to a landscape type and not applicable over large regions. This approach thus consists in post-classification correction procedures.
4.5 Land Cover Maps and Interannual Climatic Variability

Several authors indicated that NOAA AVHRR-based land cover maps could be improved by classifying multiyear NDVI time series rather than single year NDVI data. Tucker et al.\textsuperscript{98} for example, in their pioneer land cover classification of Africa, noted that errors in biome delimitation were produced because their analysis relied only on a single year of data. This was due to “...the interannual variability in vegetation response to climatic conditions”\textsuperscript{105} and the high sensitivity of NDVI to the year-to-year variations in rainfall and soil moisture.\textsuperscript{128}

The production of land cover maps from the classification of multiyear datasets raises the question of the intrinsic timescale of the concept of land cover. Clearly, daily, monthly or seasonal variations in biophysical attributes of the surface do not qualify as land cover changes. Some biophysical attributes of ecosystems also fluctuate at the interannual timescale, owing to climatic variability. Such variations are often independent of long-term climate trends. Do these fluctuations qualify as land cover changes? The title of the study by Tucker et al.\textsuperscript{129} – i.e. “Expansion and contraction of the Sahara desert...” – illustrates the uncertainty of this issue. Intuitively, it is not the boundaries of the Sahara as a geographic region, and of the desert as a distinct land cover class, which fluctuates in space from one year to the other by about 100 km. The fluctuation rather affects one of the many biophysical attributes defining a land cover type (i.e. the green biomass productivity) which responds to interannual variations in rainfall.\textsuperscript{130}

These comments suggest that the interannual climatic variability leads to changes in ecological conditions which have limited meaning in terms of land cover and that these fluctuations hide more fundamental characteristics of land cover types. This could be explained either because one year of observation lacks statistical representativity to produce a robust land cover classification, or because the remotely sensed variable used in previous land cover classifications is oversensitive to fluctuating attributes of the land surface. Indeed, NDVI is largely driven by short-term climatic characteristics more than by long-term, more intrinsic land cover characteristics. Accordingly, there are two ways to improve current NOAA AVHRR-based land cover classifications: either one averages a climate-driven, but easily accessible variable (such as the NDVI) over several years, or one measures a new variable which is sensitive to land cover quite independently from short-term climatic variations.

5 LAND COVER MONITORING

5.1 Reference State for Land Cover

Prior to detecting changes, one has to define a reference state for land cover. This can be performed in two ways: (i) on the basis of a bioclimatic reconstruction of potential climax or predisturbance vegetation or (ii) on the basis of actual observations of the state of land cover in every location at a given time. These two approaches lead to fundamentally different assessments of changes. Studies investigating the impact of land cover changes on the global climate relied on crude approximations of changes over a very long period, taking as a reference land cover prior to human disturbances.\textsuperscript{131–134} The approach is only valid if the reference state is defined through retro-projections by a model integrating all the factors constraining vegetation conditions, i.e. not only temperature and rainfall (as in climate-correlative methods) but also soil characteristics and natural disturbances such as fires. Moreover, the bioclimatic approach does not treat the temporal dimension of land cover changes explicitly: the timing, cyclicity or reversibility of changes are unknown.

By contrast, the definition of a reference state of land cover from direct observations has the advantage of clearly defining the temporal dimension of the changes detected. A baseline inventory identifies the land cover distribution as it actually occurred in a recent past. However, owing to a lack of historical data on land cover, this approach is restricted to a few decades. For the recent period (i.e. last 30 years), remote sensing techniques allow land cover mapping at broad spatial scales.\textsuperscript{135,136}

The definition of an appropriate reference state as a standard against which to measure deviations occurring in any particular year stems from a simple conceptual model of land cover, where (Equation 4):

\[
(Land\ cover\ indicator)_{year\ i} = (Land\ cover\ indicator)_{optimum\ conditions} - f(Stress\ factors) \tag{4}
\]

The land cover indicator is a continuous variable measuring biophysical properties of the surface. In the above formulation, the state of land cover for a given year is defined by reducing the optimum conditions that could be found in a site by some function of unusual stress factors (i.e. anomalous or exceptional constraints). Since most vegetation covers are in a constant state of flux, a measure of normal or average conditions would be meaningless. It is replaced here by the values of surface attributes corresponding to the optimum conditions for a certain observation period. It is assumed that these
values occur at a time when the stresses are at a minimum. Examples of natural or anthropogenic stresses that reduce these optimum conditions are droughts, exceptional fires, floods, vegetation clearing or land degradation. These values of land cover attributes corresponding to optimum conditions are indeed specific to the area for which they have been observed. They should therefore be estimated separately for every sampling unit. They can be reached occasionally (in case of fluctuating land cover conditions) or only once, either early in the observation period (in case of a continuous decrease in vegetation cover) or at the end of the observation period (in case of reforestation, vegetation regrowth, etc.). Land cover change detection measures the physical changes brought by stresses affecting the surface. This is computed from Equation (5):

\[
\text{(Land cover indicator)}_{\text{optimum conditions}} - \text{(Land cover indicator)}_{\text{year } i} \tag{5}
\]

5.2 Change Detection Methods

5.2.1 Detection Based on a Few Isolated Observations

Classic land cover change detection techniques are based on the comparison of sequential land cover maps derived from remote sensing data or other sources for the same area. For every sampling unit of the maps, the land cover categories at the two dates are compared. The comparison of successive maps does not allow the detection of subtle changes within broad land cover classes. Since most coarse spatial resolution maps usually represent only a few broad categories, only drastic land cover conversions are identified while land cover modifications remain undetected. Moreover, change maps only exhibit an accuracy similar to the product of the accuracy of each individual map.

A land cover category is an aggregate concept which is defined by a set of biophysical attributes of the surface. Rather than detecting changes on the basis of land cover categories, change detection is better performed on the basis of the continuous variables defining these categories, whether these are reflectance values measured by a satellite sensor or biophysical attributes derived by model inversion. Singh\cite{137} and Coppin and Bauer\cite{138} review techniques used for this comparison, such as image differencing, image ratioing, multispectral or multitemporal change vector analysis, image regression or multitemporal linear data transformation. Empirical studies demonstrated that there is not a single optimal change detection technique but that different techniques are best suited for different change patterns.

Recent studies have detected changes in land cover between successive dates by combining two techniques\cite{139–141} in a multistage approach:

1. postclassification comparison, that is, overlaying and comparing the two successive land cover classifications;
2. band differencing, that is, subtracting reflectances measured at the successive dates.

The postclassification comparison leads to a categorical map which indicates, for every pixel, the land cover classes at the two successive observation years.\cite{142} Its ability to characterize “from” and “to” identifiers is essential for the definition of land cover change trajectories. The disadvantage of this method is to be dependent on the classification accuracy of the maps which are compared. The second change detection technique used in combination with the postclassification comparison further increases the reliability of the final land cover change map. The band differencing method leads to a measure of change along a continuum of change intensity. It indicates the degree to which the change has modified the vegetation cover, using the surface reflectance as a proxy. While a direct evaluation of change areas is not possible with this latter method, it allows for the detection of land cover modifications as well as of land cover conversions. Several recent studies have demonstrated the good performances obtained with the band differencing method for land cover change detection.\cite{138,141,143,144}

When the two methods are combined, the unchanged areas identified based on the image differencing map are labeled based on the first-date land cover map. The unchanged areas are labeled based on the result of the postclassification comparison method. This allows reduction of the misclassifications on the final land cover change map by reducing the area for which the results of the postclassification method are retained. In other words, the results of the postclassification method are only applied to the areas which have been identified as being affected by change based on the image differencing method, which is more reliable for change detection but fails to characterize the “from” and “to” land cover classes.

5.2.2 Detection Based on Continuous Time Series

Land cover changes take place at a variety of temporal scales, for example short events with detectable effects only for a few months, modifications in seasonal trajectories of ecosystem attributes, processes that affect the land cover through several seasonal cycles and long-term, permanent changes. Land cover changes may affect, and therefore be indicated by, the phenology of the vegetation cover. The analysis of the temporal trajectories of vegetation indices based on high temporal frequency remote sensing data allows monitoring of vegetation phenology and biome seasonality.\cite{145}
Processes such as a shortening of the growing season, a dephasing of the phenology of different vegetation layers or modifications of the cover due to disturbances such as fires can only be detected if interannual changes in the seasonal trajectories of vegetation covers are analyzed. For any landscape with a strong seasonal signal, the detection of interannual changes needs to explicitly take into account the fine scale temporal variations. If data from only one or a few dates a year are used to measure interannual changes, the undersampling of the temporal series hinders the change detection accuracy and might lead to the detection of spurious changes.\(^\text{(83)}\)

A quantitative evaluation of differences in seasonal development curves of remotely sensed data was applied for land cover change analysis by some authors.\(^\text{(146)}\) A measure of the deviation in seasonal trajectories can be computed between successive years. Subtle processes of land cover change can be detected this way. Results of these two studies in Africa suggested that land cover changes mostly involve erratic variations in land cover conditions due to droughts, temporary modifications in seasonality, shifts in the timing of rains and episodic events to which most ecosystems display a high resilience. In a study that opens a new line of research, Goward and Prince\(^\text{(147)}\) provided empirical data, measured by remote sensing, that indicate some persistence or lag between vegetation activity and climate dynamics. In some ecosystems, the response time of vegetation to short-term climatic fluctuations might provide useful information on key characteristics of the ecosystem, such as its level of degradation.

In addition to the monitoring of remotely sensed indicators of land cover changes, one can integrate a monitoring of its proximate causes or of other surface processes closely associated with the state of the vegetation cover. The best example of such process for tropical ecosystems is biomass burning. Recent research has improved the ability to monitor active fires and burnt areas by remote sensing.\(^\text{(148,149)}\) On one hand, land cover changes may result from repeated biomass burning or be caused by a change in the fire regime. On the other hand, ecosystem degradation is likely to lead to a modification of the seasonal distribution and spatial patterning of fires as the diffusion of fires through the landscape will be altered.

5.3 Mapping Ecosystem Disturbances

The ecological variable of interest is often the degree of ecosystem disturbance, including both natural and anthropogenic, as well as recent and past disturbances. Disturbance refers to “any relatively discrete event in time that disrupts ecosystem, community or population structure, and changes resources, substrate availability or the physical environment”.\(^\text{(150)}\) In forest ecosystems, particular attention is paid to events that create an opening in the canopy.\(^\text{(151)}\) Any vegetation cover or landscape mosaic can be conceptualized as following a development trajectory until the impact of some disturbance disrupts this development. The cover type is then forced into another trajectory, more or less remote from the initial one, depending on the magnitude, type, duration and return-interval of the disturbance. Terms like forest degradation and forest fragmentation are commonly found in the literature to describe such processes. The first expression, forest degradation, refers to changes to the forest which negatively affect the state of the forest ecosystem and, in particular, lower its biological productivity. A forest cover is termed fragmented when it is “... broken down into disjunct parts by conversion of parts of the cover to non-forest land cover types”.\(^\text{(152)}\)

The repetitive or episodic impact of disturbances on landscapes is a highly dynamic process. It is highly variable since it depends on the forcing agent (e.g. a typhoon or a fire). The detection and modeling of ecosystem disturbance therefore requires successive observations of surface conditions with a high time frequency. Repetitive observations at a scale of an entire country or a region is generally not feasible because:

1. time series of broad scale remote sensing observations (e.g. from the NOAA AVHRR sensor) date back less than two decades;
2. some areas are affected by a nearly permanent cloud cover which makes satellite sensor observation in the optical domain most difficult.

An alternative, more feasible, approach consists in defining monotemporal indicators of ecosystem disturbances. Candidate variables that could be detected by remote sensing are, for example, tree density, the spatial heterogeneity of the vegetation cover and surface moisture status (i.e. water stress at the level of the canopy). To infer the impact of disturbances on vegetation cover through a monotemporal approach requires some assumptions on the initial conditions of the landscape. Since vegetation covers are in a constant state of flux, such assumptions are easier to formulate for long-term studies, e.g. by defining, as the reference state, the vegetation cover before any human impact rather than the vegetation cover as it was supposed to be a few decades ago.

5.4 Land Cover Monitoring Systems

Some global-scale systems for monitoring tropical deforestation and dryland degradation have been put in place. Quantitative estimates of rates of change over the recent period (i.e. the last few decades) have been collected systematically for forest ecosystems by three international projects: “Forest Resource
require further developments for a more robust approach.

for monitoring woodland degradation would probably for tree size. The application of this type of approach for the estimation of tree density and cover but poor background), weighted by their relative areas. Inversion is modeled as a linear combination of the signatures of illuminated background, shadowed tree and shadowed shadow on the background. The reflectance of a pixel is modeled geometrically as a group of objects casting a strong interaction between erratic fluctuations in rainfall due to climatic variability and anthropogenic changes in vegetation cover. Hulme and Kelly have attempted to separate the two effects by comparing time series of a remotely sensed VI and rainfall data. They concluded that longer time series of observations would be needed before reaching any firm conclusion. Only local-scale studies backed up by field work and by time series of aerial photographs and satellite images produce convincing evidence of localized dryland degradation.

To date, there is no attempt to apply such systematic measurements at a global scale.

6 PERSPECTIVES

6.1 Model Inversion

Physically-based approaches, relying on model inversion, have been developed. In these methods, a scene model is constructed to describe the form and nature of the energy and matter within the scene and their spatial and temporal order. This scene model is coupled with an atmospheric and a sensor model. This coupled remote sensing model is then inverted to infer, from the remotely sensed measurements, some of the properties or variables of the scene which were unknown. Concerning complex landscapes, these methods are not yet sufficiently robust to be applied routinely for a large-scale monitoring of land cover changes, because it is difficult to represent adequately in a model the natural variability in landscape structure and composition. For example, Franklin and Strahler applied a model inversion approach to generate regional estimates of tree size and density in West Africa, using Landsat TM data. They used the Li-Strahler canopy reflectance model. A woodland stand is modeled geometrically as a group of objects casting shadow on the background. The reflectance of a pixel is modeled as a linear combination of the signatures of the major scene components (i.e. illuminated tree crown, illuminated background, shadowed tree and shadowed background), weighted by their relative areas. Inversion results over a sample of observations were satisfactory for the estimation of tree density and cover but poor for tree size. The application of this type of approach for monitoring woodland degradation would probably require further developments for a more robust approach.

In the future, radiative transfer models should allow the scientific community to derive, using a physical approach, surface parameters such as: hemispherical albedo, land surface temperature and emissivity, soil moisture, snow cover, LAI, net primary production, total biomass, evapotranspiration, incident short-wave radiation, outgoing long-wave radiation, PAR and fraction of absorbed photosynthetically active radiation (FPAR). These parameters are important input variables in ecosystem models such as Soil-Vegetation-Atmosphere-Transfer (SVAT) models, energy and water models, biogeochemical models, or resource management models.

The dependence of land surface reflectance on sun and sensor viewing geometry is governed by the bidirectional reflectance distribution function (BRDF). Multiple-view-angle data of the Earth’s surface (which will be provided by future satellite sensors) will permit the exploitation of the BRDF of surfaces to extract a greater number of surface attributes by remote sensing. Actually, as the reflectance distribution of vegetation is strongly anisotropic, multiple-view-angle observations of terrestrial ecosystems contain additional and unique information beyond that acquired with nadir or single-angle spectral measurements alone. Variations in the BRDF of vegetation results primarily from differences in canopy- and landscape-level structural characteristics (such as ground coverage and spatial distribution of vegetation, crown geometry, LAI, leaf angle distribution, foliage clumping), along with leaf biogeochemical and soil textural attributes. Multi-view angle measurements of the vegetation BRDF will allow improved retrieval of important canopy structural characteristics (e.g. LAI) and biophysical variables (e.g. fraction of PAR absorbed by plant canopies). This opens promising avenues for a more quantitative characterization of the terrestrial biosphere from space.

6.2 New Sensors and Multisensor Approaches

The coming years will see an increase and qualitative improvement in the Earth observation systems on orbit. These new sensors will include both very fine spatial resolution systems (i.e. a few meters) with a low spatial coverage and high temporal frequency, coarse spatial resolution systems, with an increase in spectral bands, sensor calibration and better georeferencing of the data. The potential for multisensor analysis (i.e. combining data from different sensors) will increase greatly. Three types of combinations will be interesting:

1. fine and coarse spatial resolution data, to combine a detailed view of the land surface over a few representative locations with an exhaustive view of the surface at a coarser spatial resolution;
2. data at approximately the same spatial resolution (fine or coarse) but from different sensors to increase the temporal frequency of coverage of a given area;
3. data at approximately the same spatial resolution but in different spectral ranges (visible, thermal, microwave) to describe more comprehensively surface processes.

Multisource data-fusion techniques are being developed for vegetation classification. Fusion of complementary data leads to a more consistent recognition of vegetation patterns. Depending on where the combining operations take place in the information extraction process, data fusion is categorized at four different levels: signal, pixel, feature and decision level. There are four types of fusion methods: statistical, fuzzy logic, Dempster–Shafer evidence theory and neural network. The neural network approach has the inherent ability to incorporate multisource data and also the capability to identify mixed pixels. Data-fusion techniques have led to a number of operational applications, e.g. to delineate land cover at appropriate thematic and spatial resolutions to support a quantitative inventory of forest carbon stocks in North America.

Polar regions are those surrounding the North and South Poles and situated within the Arctic and Antarctic Circles of the Earth. The polar regions are characterized by environments harsh to human and other organisms: low mean annual temperature and long nights and extensive snow and ice cover in winter. Because of the harsh conditions and poor accessibility, assessment of different aspects of the polar environment, such as light, temperature, snow and ice cover, soil and vegetation, largely relies on information acquired by remote sensors, i.e. airborne- and satellite-borne electromagnetic instruments. This article briefly describes how and to what extent polar environmental information is currently derived through remote sensing methods.

## 1 INTRODUCTION – POLAR ENVIRONMENT, CHARACTERISTICS AND IMPORTANCE

Polar environments include both polar oceans and polar land environments. The current article will be devoted only to polar land environments in both Arctic and Antarctic regions. Polar land environments are characterized by the cold climate, the extreme seasonal variation in incoming solar radiation and the consequent drastic seasonal changes in air and surface temperatures. As a result, polar regions are covered by snow and other various forms of ice at least during their long winter. In summer snow and ice may melt if the incoming radiation is sufficiently large and the environment...
becomes sufficiently warm. In places where the ground surface eventually becomes snow and ice free, the low surface albedo of bare soil further accelerates snowmelt in the surrounding areas. With abundant solar illumination and soil moisture, vegetation flourishes on the snow-free surface during a very short period. Because water is frozen either seasonally or permanently, the polar land environments are the main land component of the terrestrial cryosphere. During the summer melt season, snow cover and glaciers release large amounts of fresh water. Seasonal and permanent frost in soils reduces the amount of water that can be stored in soils. By reducing infiltration, frozen soils can dramatically increase the runoff generated from melting snow. Assessment of the polar environment by remote sensing should focus on the investigation of surface changes related to these seasonal phenomena. With global climate change being a crucial issue in environmental studies, assessment should also be focused on inter-annual changes of the main seasonal phenomena in polar regions. Because global climate modeling studies indicate that the effects of climate changes may be amplified at higher latitudes owing to strong positive feedback of snow and ice to the surface energy balance, the assessment of long-term changes in polar regions becomes extremely important. These studies will improve our understanding of the surface processes in the polar regions and the impact of the interaction among the cryosphere, the weather and climate system, the geosphere and the biosphere.

The main issues to be discussed in this article include: (1) remote sensing of surface albedo and surface temperature in relation to snow distribution; (2) remote sensing of surface soil thaw and freeze status; (3) remote sensing of other forms of ice existing on land surfaces, including glaciers, ice sheet, lake ice and river ice; (4) remote sensing of soil moisture in tundra; and (5) remote sensing of vegetation and forest fire.

2 REMOTE SENSING OF SNOW AND ICE SURFACE PROPERTIES AND SNOW AND ICE-COVERED AREAS

Among various snow and ice surface properties, albedo and surface temperatures are of the most significant importance in meteorological and climate research. Albedo is defined as the ratio of the upwelling shortwave irradiance at the surface to the incident shortwave irradiance. Surface albedo is an important geophysical parameter because it determines the shortwave energy exchange at the Earth’s surface. For weather forecasting and global climate change modeling, accurate albedo estimates are required by a general circulation model (GCM). In the polar regions, the albedo of snow is much greater than that of any other surface cover. Because of its broad geographic distribution, snow has an important influence on the global radiation budget and global climate. The possible importance of snow and ice albedo feedback to climate change was first recognized by Croll. This positive snow and ice albedo feedback is easily understood. The onset of surface melting leads to a reduction of albedo. The latter increases the absorption of shortwave energy at the surface, and results in further enhancement of the melting rate. This mechanism has proven very important in numerous simulations of global warming. Snow and ice albedo is especially important in warm seasons when the solar illumination is one of the dominant factors of surface energy exchange. The transition from snow-covered to snow-free conditions can be very rapid. For example, tundra and prairie snow in Alaska can melt completely in 2 weeks on average. Monitoring changes of snow cover over large areas in polar environments during the melt season when access to these remote areas is extremely difficult is almost impossible without remote sensing techniques.

Temperature is another parameter of vital meteorological and climatological importance because it is a dominant factor in determining the outgoing longwave radiation from the surface and the sensible and latent heat exchange between the surface and the atmosphere. In the cold winter, the surface temperature in the polar regions can be extremely low. During the melt season, the snow and ice surface is close to isothermal conditions although there are still certain diurnal changes. After snow melt, the surface temperature of bare soil can increase rapidly owing to the low albedo of bare soils. Since albedo is the wavelength-integrated hemispheric reflectance in solar spectra, it can be remotely sensed at visible and reflective infrared (IR) wavelengths under clear sky conditions. Surface temperature can be estimated from its brightness temperature if the surface emissivity is known. Because the emission from the terrestrial surface peaks at thermal infrared (TIR) wavelengths and surface emissivity is close to unity at those wavelengths, surface temperature can be estimated with remote sensors operating at those wavelengths. Because of the atmospheric effects, remote sensors often operate in narrow spectral windows where the atmospheric effects are minimal. These sensor response windows are always much narrower than the solar spectral region or the TIR region. Derivation of surface albedo and temperature from spectral reflectance and emission obtained from remote sensing not only requires atmospheric correction of the remotely sensed data, but also needs basic knowledge of the spectral characteristics of snow- and ice-covered surfaces. In addition, cloud cover can be a problem in remote sensing of snow and ice surfaces because clouds are similar
to snow and ice surfaces in many respects: they are highly reflective in solar spectra and can appear as cold objects when sensed in TIR wavelength bands. Therefore, separation of snow and ice surface from clouds is necessary for remote sensing of snow and ice surface properties under cloudy conditions. Since strati are common in winter and cumuli are dominant in summer in polar regions, remote sensing in solar reflective and TIR regions reveals its inherent weakness when frequent monitoring of snow and ice is needed. With much stronger penetration capability, microwave techniques can be used to provide all-weather and day-and-night information of the polar regions.

2.1 Optical Properties of Ice

Detailed study of the wavelength dependence of spectral reflectance and emissivity on snow and ice properties would lay a firm foundation of remote sensing of snow and ice properties that are of vital interest. These properties depend on the optical properties of ice.

Snow is a collection of ice grains and air and when at 0°C it also has a significant fraction of liquid water. Snow also includes particulate impurities – dust, soot, pollen and other plant material – and chemical impurities – small amounts of major cations and anions. Thus the optical properties of snow depend on the bulk optical properties and geometry of the ice grains, the liquid water inclusions and the solid and soluble impurities. In the visible and near-infrared (NIR) wavelengths, the bulk optical properties of ice and water are very similar. The reflectance and transmittance of the snow pack in this wavelength region depend on the wavelength variation of the refractive index of ice, the grain size distribution of the snow, the depth and density of the snow pack and the size and amount of the impurities.

In the microwave region, water is much more absorptive than ice, so at those wavelengths, minute amounts of water dramatically change the electromagnetic signature of the snow pack.

The most important optical property of ice, which causes spectral variations in the reflectance of snow in the visible and NIR wavelengths, is that the absorption coefficient (i.e. the imaginary part of the refractive index) varies by seven orders of magnitude at wavelengths from 0.4 to 2.5 µm. Normally, the refractive index is expressed as a complex number, \( n + ik \). Figure 1(a) and (b) shows the real and imaginary parts, respectively, of the refractive index for ice and water. The importance properties to note are (1) the spectral variation in real part \( n \) is small and the difference between ice and water is not significant; (2) the absorption coefficients \( k \) of ice and water are very similar, except for the region between 1.55 and 1.75 µm, where ice is slightly more absorptive; (3) in the visible region, \( k \) is small and ice is transparent; and (4) in the NIR region, ice is moderately absorptive, and the absorption increases with increase in wavelength.

Using a radiative transfer-based snow model, the spectral reflectance of snow can be calculated. Figure 2 shows the spectral reflectance of pure deep snow for visible and NIR wavelengths, for snow grain radii from 50 to 1000 µm. This snow grain radius range represents a range for new snow to spring snow, although the grain clusters in coarse spring snow can exceed 0.5 cm in radius. Because ice is so transparent at visible wavelengths, increasing the grain size does not appreciably affect the reflectance. In the NIR region, however, ice is moderately absorptive. Therefore, the reflectance is sensitive to grain size, and the sensitivity is greatest at 1.0–1.3 and at 1.55–1.75 µm. Because the ice grains are strongly forward scattering at NIR wavelengths, the reflectance increases with increase in illumination angle (Figure 3), especially for larger grains.
According to the radiative transfer model, the presence of liquid water in the snow does not by itself affect the reflectance. The observed changes in reflectance during snow melt result from the increased crystal sizes and from an effective size increase caused by the two-to-four grain clusters that form in wet unsaturated snow.\(^{11,12}\)

At visible wavelengths, reflectance is insensitive to snow grain size, but is affected by two variables, finite depth and the presence of absorbing impurities. For pure snow with grain radius \(r = 1000\) µm, the reflectance is perceptibly reduced when the snow depth is reduced to 100 mm snow water equivalence. Warren and Wiscombe\(^{10}\) also showed that minute amounts of absorbing impurities reduce snow reflectance at visible wavelengths, where pure ice is highly transparent. Their calculation shows that soot concentrations as low as 0.1 ppmw (parts per million by weight) are sufficient to reduce reflectance. The effect of the absorbing impurities is apparently enhanced when they are inside the snow grains because refraction focuses the light on the absorbers.\(^{13,14}\)

### 2.2 Cloud Mask – Use of Spectral Difference at Reflective Infrared Wavelength Regions

Both snow and clouds have high reflectance in visible wavelength. This is understandable because snow pack is composed of snow grains and clouds consist of either water droplets or ice crystals. Because of their spectral similarity, discrimination of snow and clouds can be a challenging task in remote sensing for snow and ice applications. Fortunately, snow and cloud discrimination is possible using the spectral information in the region between 1.55 and 1.75 µm, where ice is more absorptive and reflectance is most sensitive to ice grain sizes. In this wavelength region, water clouds have higher reflectance than snow, because water droplets are less absorptive. Also, ice clouds (such as cirrus) are more reflective than snow because the former is composed of ice crystals (a few micrometers at most) that are much smaller than the snow grains in regular snow pack (50–1000 µm). Therefore, the bands of the Landsat Thematic Mapper (TM) allow snow–cloud discrimination.\(^{15,16}\) Using color images composed of TM bands 2, 5 and 7, clouds can clearly discriminated from snow by spectral features. A new example given by Riggs et al.\(^{17}\) uses wavelength bands at 0.547, 0.869 and 1.609 µm to form a color composite which clearly shows the difference among sea ice, open water and clouds.

### 2.3 Measurement of Snow Properties by Remote Sensing

The advanced very high-resolution radiometer (AVHRR) on the National Oceanic and Atmospheric Administration (NOAA) operational polar orbiting satellites scans across-track up to 56° off nadir and therefore views the surface at widely varying view angles. The AVHRR sensor consists of one visible, one NIR and two TIR channels, and also one mid-infrared (MIR) channel that is sensitive to a combination of thermal and reflected solar fluxes. The visible and NIR radiance measurements of the AVHRR sensor have been used for mapping snow-covered areas.\(^{18}\)

In the late 1980s, the National Aeronautics and Space Administration (NASA) started an ambitious remote
sensing program, the Earth Observing System (EOS). EOS is designed to provide long-term observations in the area of climate and terrestrial and marine ecosystems and the supporting information system necessary to develop a comprehensive understanding of how the Earth functions as a unified system. After a continuous, decade-long effort, NASA is finally about to launch Terra, the EOS “flagship”. Terra will begin collecting a new global data set on which to base future scientific investigations on our complex home planet. The moderate resolution imaging spectroradiometer (MODIS) is one of the key instruments on Terra and her successors. MODIS will acquire reflection and emission of the Earth system daily in 36 bands at spatial resolutions of 250 m (bands 1–2), 500 m (bands 3–7) and 1000 m (bands 8–36).

The multi-angle imaging spectroradiometer (MISR) is another key instrument on Terra. MISR will image the Earth simultaneously at nine different angles in each of four color bands. With MISR, it is feasible to study every aspect of the Earth’s climate system that scatters sunlight differently at different angles.

The NASA science team will use MODIS data to develop a global snow map as a routine product. The global snow cover will be mapped daily at 500-m resolution using MODIS bands 1, 2, 4 and 6. A pixel will be designated as snow covered if it is approximately 50% or more snow covered. The expected accuracy of the MODIS-derived snow map will vary with land cover type. According to field, aircraft and satellite measurements, the accuracy is 15% in forest, 10% in mixed agriculture and forest areas and 5% in prairie areas, barren and sparsely vegetated areas, wetlands, tundra and permanent snow and ice fields.

The AVHRR images are also used for the derivation of surface spectral albedo in polar regions under clear sky conditions with the atmospheric and surface anisotropic effects corrected, and the resulted narrow-band reflectances are further converted into a broad-band albedo (0.4–3.0 μm). Comparison of the AVHRR-derived surface albedo over the Greenland Ice Sheet with field measurements indicates that before the onset of snow melt, agreement is good (<5%) between the satellite-derived and field measured surface albedo. After melt begins, it is difficult to compare satellite values with the field data owing to melt water ponding on the ice sheet surface. Because AVHRR has a nominal spatial resolution of 1 km, it could not map the details of surface albedo in mountainous areas where variations in solar illumination make the derivation of snow surface albedo more difficult, or during snowmelt when the surface albedo shows greater spatial variations. Sensors with finer spatial resolution are needed for such cases. Shi et al. used images from the Landsat TM to derive surface albedo with the help of a digital elevation model (DEM).

The accuracy of the satellite-derived surface albedo depends in part on the accuracy of the primary atmospheric input variables used in the atmospheric correction. Most of the current space-borne sensors, such as AVHRR and Landsat, themselves, are not able to provide sufficient information on atmospheric conditions (especially the amounts of aerosols) necessary for accurate albedo derivation. The accuracy of the satellite-derived surface albedo also depends on the appropriateness of surface anisotropic correction. In the previously mentioned example of derivation of surface albedo using AVHRR images, Stroeve et al. used a radiative transfer model to simulate the anisotropy of the snow surface reflectance.

In the EOS era, because measurements will be made in a large number of spectral bands through MODIS and over a wide range of viewing directions through both MODIS and MISR, the atmospheric conditions and surface anisotropy can be accurately derived from those sensors. Consequently, surface albedo can be more accurately estimated. In fact, the bidirectional reflectance distribution function (BRDF)/albedo product is listed as one of the high-level products to be derived. The BRDF provides a quantitative representation of surface reflectance for any type of surface, including Lambertian and anisotropic surfaces.

MODIS BRDF/albedo is a general-purpose product to be derived from Terra satellite instruments. Because of the large number of spectral channels available on the MODIS sensor and the various sensor viewing angles associated with MISR, the combination of MODIS and MISR is superior to any existing satellite sensors for correction of the atmospheric and surface anisotropic effects. Two sub-types of albedo products will be produced: (1) simple nadir broad-band surface albedo for global climate models that require shortwave energy partitioning; and (2) multiangle spectral albedos for other advanced MODIS products. Meanwhile, the BRDF will be generated. The BRDF is a key element in the derivation of surface albedo because it specifies the behavior of surface scattering as a function of illumination and view angles at a particular wavelength.

2.4 Mapping Snow Depth Distribution Using Sequences of Snowmelt Images and Energy Balance Model

To assess the hydrological or climatic impact of tundra and prairie snow, the most fundamental information needed is the snow depth distribution. The depth distribution evolves and changes throughout the winter, but typically reaches a maximum near the end of winter. This is the initial distribution for modeling the spring run-off, assessing winter frost penetration under the snow and describing the evolution of the albedo as the snow melts.
The end-of-winter snow depth distribution in tundra, steppe and prairie can be recovered from a sequence of images of the snow-covered area acquired during the snowmelt if an energy balance model is used to calculate the melt rate.\(^{23}\) Images acquired at visible and NIR wavelengths are the most straightforward means for mapping these snow-covered areas because the snow has a much higher albedo than the surrounding darker ground. However, frequent occurrences of clouds over tundra areas such as Alaska’s Arctic Slope reduce the probability of obtaining a suitable suite of images during the rapid melt, which often takes less than 10 days. Gaps in the image sequence can only be bridged by images acquired by microwave sensors that are capable of mapping the Earth’s surface even under overcast conditions and during periods of dark.

Using Cline’s idea, we collected a snowmelt sequence at a study area at Ivotuk, Alaska, during the 1999 melt season, using a combination of air photographs, Système Probatoire Pour l’Observation de la Terre (SPOT) and AVHRR visible images acquired under clear sky conditions, and Earth Resources Satellite (ERS) synthetic aperture radar (SAR) and RADARSAT SAR images acquired in both clear and cloudy conditions.\(^{24}\) The combined image sequence depicts the details of a 10-day snowmelt process. The results will be used with a melt model to recover the end-of-winter snow depth distribution in the study area. The study also shed light on the relation between radar backscatter and snow pack conditions.

### 2.5 Use of Synthetic Aperture Radar Interferometry for Investigation of Redistribution of Snow

Recently, satellite SAR interferometry, available via the European Space Agency (ESA) First ERS-1, has provided all-weather and day-and-night capabilities for detecting subtle surface changes.\(^{30}\) Using satellite SAR interferometry, we produced the basic pattern of redistribution of wind-drifted snow in the Alaskan Arctic region.\(^{31}\) The coherence image of an interferogram measures the resemblance of radar phases between two acquisitions a few days apart in the vicinity of each pixel location. Formation and evolution of sastrugi, or snow dune, on a new snow slab with a certain thickness can significantly reduce the phase coherence. As a result, areas and times with and without significant snow accumulation and drifting are revealed very clearly on the coherence images of the interferograms. After a new snow fall and a following strong west wind event in February 1994, patterns of relatively high phase coherence on the windward slopes and low coherence on the leeward slopes and vast tundra form the most striking features on the interferograms which cover the middle of February through the middle of March 1994. These patterns show less accumulation of new snow on the windward slopes due to wind acceleration and an opposite process on the leeward slopes. This finding not only agrees with previous field investigations, in the sense that small-scale terrain relief of the order of meters actively affects the redistribution of wind-drift snow on the tundra, but also leads to an improved knowledge that large-scale topography with surface relief of the order of tens to hundreds of meters plays a key role in determining the larger scale redistribution patterns of new snow fallen on the North Slope of Alaska. The interferograms also identify an event with bands in wind, i.e. bands a few kilometers wide and hundreds of kilometers long, possibly caused by bands of different concentrations of ice particles suspended in the air. This is a phenomenon that observers noticed in previous field investigations but were never able to have a big picture of it.

### 2.6 Use of Multi-frequency Polarimetric Synthetic Aperture Radar

As mentioned in the previous section, the application of SAR images with single wavelength and single polarization in environmental studies requires terrain correction of the SAR images to remove the geometric distortions inherent in the slant range mapping of radar sensors, and to normalize radar backscatter on a sloping surface.\(^{32,33}\) Unlike single polarization SAR, polarimetric SAR provides information in full polarization, including horizontal transmit, horizontal receive (HH), vertical transmit, vertical receive (VV), horizontal transmit, vertical receive (HV) and vertical transmit, horizontal receive (VH). The polarimetric data allow pixel-by-pixel derivation of the complete scattering matrix and thereby detailed information about the geometric structure and dielectric property of a target.\(^{34}\) The concept of application of a combination of multifrequency and full polarization to map snow is investigated in the SIR-C/X-SAR (shuttle imaging radar-C and X-band synthetic aperture radar) experiment. SIR-C/X-SAR is a joint project between NASA, the German Space Agency (DARA) and the Italian Space Agency (ASI). SIR-C provides radar polarimetric images simultaneously at the L-band (24 cm) and C-band (5.6 cm). The X-band (3 cm) SAR with VV polarization provides information in the third frequency. Because NASA space shuttles cover only the mid-low latitude, no high-latitude examples are available.

Using SIR-C/X-SAR, Shi and Dozier\(^{35}\) developed a procedure to map wet snow without using a DEM. Although the experiment was made over site at a mid-latitude site at Mammoth Mountain, California, the procedure is potentially applicable to polar regions.
The basic ground cover types during the experiment include coniferous forest, short vegetation such as brush and grass, bare soil, snow and lake. The directly measured polarimetric values at each pixel are used to derive 20 polarimetric quantities at the L- and C-bands and 10 backscatter ratios between different frequencies. Because the derived polarimetric quantities and backscatter ratios are various forms of ratios among the basic polarimetric measurements on a pixel basis, the terrain effects are cancelled. Consequently, the derived values can be used for snow mapping without using a DEM. Using those derived quantities, a decision tree classifier (DTC) was implemented based on training sets. On April 17 1994, when the snow was wet, the SAR-derived snow map was about 77% as accurate as the TM binary classification. The example demonstrates the potential of multifrequency SAR polarimetry in snow mapping.

3 REMOTE SENSING OF FREEZE AND THAW STATUS OF THE SURFACE

3.1 Use of Passive Microwave Brightness Temperature and Radar Backscatter to Detect Surface Freeze and Thaw Status

Measurements of the Earth’s surface in the microwave regions is largely insensitive to weather conditions and solar illumination. Microwave sensors appear ideal to measure the properties of the cryosphere because the microwave signal is sensitive to the dielectric constant of surface materials, which in turn is highly sensitive to the phase of water, ice or liquid.

Passive microwave sensors have demonstrated sensitivity to snow and surface freeze–thaw transitions. Ground-based measurements indicate that the surface brightness temperature increases substantially when wet soil is freezing, owing to a significant increase in emissivity even though the soil temperature is decreasing.\(^{36,37}\) When multiple-frequency microwave brightness temperature data are available, such as those acquired by the Nimbus 7 scanning multi-channel microwave radiometer (SMMR), the spectral gradient of brightness temperature provides further information of the soil frozen and thaw status. The 10.7–37 GHz brightness temperature spectral gradient is especially useful because wet soils have high brightness temperature spectral gradient values whereas frozen soils have low values.\(^{38–40}\) These facts make it feasible to classify four types of soils, frozen, hot (and dry), wet (and cool) and mixed soils, using spaceborne microwave radiometers.\(^{40}\) The major problem with passive microwave radiometers is that their spatial resolution is too coarse (>10 km) to obtain information adequate for the analysis of hydrological processes at relatively small scales.

Also having all-weather and day-and-night capabilities, satellite SAR maps the surface at spatial resolutions much finer than passive microwave radiometers. The radar backscatter is very sensitive to the freeze and thaw status of moisture in soil and vegetation because freezing results in a dramatic decrease in the dielectric constant due to the cessation of the rotation of the polar water molecules. Ground-based scatterometer measurements show a 3–6 dB drop in surface backscatter coefficients when bare soil freezes.\(^{36,37}\) A similar drop in backscatter was observed with freezing at a forest site in interior Alaska using C-band, VV polarization SAR imagery acquired from ERS-1.\(^{41}\) Radar backscatter was observed to rise by 4 dB in Siberia during the spring thawing process using time series of the ERS scatterometer and SAR images.\(^{42,43}\)

3.2 Use of Synthetic Aperture Radar Interferometry to Study Frost Heaving and Thaw Settlement

SAR interferometry is also used to detect frost heaving of the active layer over permafrost.\(^{44}\) Permafrost plays an important role in polar and global climatology, primarily owing to its unique characteristic in the ground thermal regime, inhibition of the groundwater recharge and movement, enhancement of runoff,\(^{45}\) restriction to plant growth, and sensitive response to moisture and trace gas exchanges (e.g. CO\(_2\) and CH\(_4\)) between the atmosphere and polar soils. Recent studies show that global warming can turn the permafrost region from a net carbon sink to a source, thus acting as a positive feedback to global climate change.\(^{46}\) Monitoring changes in the timing and duration of the active layer freeze–thaw cycle and thickness of the active layer provides an extremely sensitive way to study climatic change.\(^{47}\) However, it is difficult to monitor the changes over large areas through in situ measurements under the Arctic weather conditions. A study site was chosen near the Toolik Lake within the Ilimivait watershed at the foothills of the Brooks Range, Alaska. The site is located in a region of continuous permafrost. The low boundary of the permafrost is between 250 and 300 m below the surface. Although the topography is gentle and the elevation range is small, the thickness of the active layer over permafrost varies significantly as a function of hill slope position. A deformation pattern was derived from a pair of ERS-1 SAR images obtained on October 4 and August 31, 1995. Terrain effects on fringes in both interferograms were removed using a third interferogram made from a pair of ERS-1 and -2 SAR images acquired on October 4 and 5, 1995. During the period time, the active layer began to freeze, and hence the surface was
uplifting. In the resulting interferogram (Figure 4), at the top of hills and along main river channels, during the early freezing season between later August and early October, frost heave is 1–1.5 cm higher than at the valley bottom. This pattern matches well the spatial variations of the thickness of the active layer near the Toolik site. According to Walker et al., the active layer is around 0.7–1.0 m thick near the top of the hills, and reduces to 0.3–0.4 m at the valley bottom. The active layer along the river channels is also thick because of the thermal effects of stream water. The derived pattern of differential frost heaving can be explained by freezing of about half of the active layer with a water content up to 60% by volume and a thickness difference between 30 and 70 cm.

Figure 4 Color composite of interferograms near Toolik Lake, Alaska. The green component of the composite is made of a differential interferogram derived from a pair of SAR images acquired on August 30 and October 4, 1995. The blue component is made of the coherence image of the same interferogram. The red component is made of a differential interferogram derived from a pair of SAR images acquired on August 30, 1995 and August 15, 1996. Terrain effects on fringes in both interferograms have been removed using a third interferogram made of a tandem pair of ERS-1 and -2 SAR images acquired on October 4 and 5, 1995, respectively. The green tone at the top of the hills and along the river channels represents a frost heave 1–1.5 cm higher than its surrounding red toned area for the period between August 30 and October 4, 1995.

4 REMOTE SENSING OF GLACIER, LAKE ICE AND RIVER ICE

4.1 Use of Satellite Synthetic Aperture Radar Images for Mapping Polar Ice Sheets

Satellite SAR images have been used to map ice sheets in Greenland and in Antarctica. ERS-1 SAR images have been used to form a mosaic of the ice sheet in Greenland. The mosaic reveals the basic zonation of the ice sheet. The zones have backscatter signatures related to the structure of the snowpack, which varies with the balance of accumulation and melt at various elevations. From the center of the ice sheet towards its edge, there exist four distinct zones (or facies). The central part is the dry snow facies. The dark signal in radar backscatter of this zone results from the low-volume scattering of fine, dry snow grains in the cold, deep snow pack of the dry snow facies. Outside the dry snow facies is the percolation facies. In the percolation facies, where vertical ice fingers or pipes and horizontal ice lenses develop, a bright radar signature is caused by strong double bounce of the radar beams between the ice pipes and ice lens, and surface scattering from the ice surfaces. Further outside, the dark appearance of glaciers with moist snow cover is the consequence of the strong microwave absorption within the moisture-rich snow pack. The bare ice in the outmost part of the ice sheet reveals a moderate backscatter because of lack of the microwave-absorptive moist snow layer. The boundaries of zones can be accurately located on the mosaic. The SAR images also reveal a large flow feature in northeast Greenland that is similar to ice streams in Antarctica and may play a major role in the discharge of ice from the ice sheet.

In normal operation, all of the current and previous polar orbiting satellite SARs have been oriented to the right side of the orbital plane to maximize coverage of the Arctic regions. This normal operation leaves a relatively small area without coverage at the North Pole and a larger hole at the South Pole. In order to obtain coverage of Antarctica, a special in-orbit 180° yaw maneuver of the Radarsat was performed to re-orient the satellite to the left-looking configuration. The new orientation is referred to as the Antarctic Mode and it covers the entire Antarctica. Figure 5 shows the coverage of Antarctica during the Antarctic Mode.

The Antarctic Mode was implemented during the Radarsat Antarctic Mapping Project (RAMP) in September and October 1997. Approximately 4000 SAR images were collected during that time period. The image data were combined with a recently created DEM for removing geometric distortion and making radiometric normalization. The results form a terrain-corrected SAR mosaic of the entire ice sheet of Antarctica. The mosaic reveals
extraordinary details about the Antarctic ice sheet. It provides a new view of Antarctica and permits quantitative analysis of surface properties over all of East and West Antarctica (Figure 5).

In addition, Radarsat SCANSAR captured the break-off of a large tabular iceberg from the Ronne Ice Shelf, Antarctica, that occurred over the period from October 20 to November 1, 1998 (at http://www.asf.alaska.edu/user_serv/feature.html). The iceberg, identified as A-38, measures approximately 150 \times 50 \text{ km} (larger than the area of the state of Delaware) and is seen to break up into smaller pieces as it drifts northwards. The resulting pieces were identified as A38A, -B, and -C. The northernmost section of the iceberg, A38B, is seen to drift 50 km over the 10-day period involved in this animation. Note the top left section of ice shelf that breaks off after being struck by the main iceberg. The image showing the ice shelf prior to the iceberg breaking off was acquired approximately 1 year earlier.

### 4.2 Use of Altimetry to Measure Ice Sheet Topography and Mass

Altimeters are nadir-viewing instruments which transmit short-duration electromagnetic pulses with known power in a pencil beam towards the Earth’s surface, then measure the reflected energy in a number of time gates. The signal amplitudes in successive gates create a waveform. The time delay until receipt of the reflected signal, when coupled with a knowledge of the velocity of propagation through the ionosphere and wet troposphere, can be converted to an accurate measurement of the elevation of surface topography, given that the orbit ephemeris is accurately determined.

Satellite radar altimetry has a history of more than two decades. The first such instrument was on board GEOS 3 in 1975. Because it only covered areas between 60° north and south latitude, it missed almost all ice sheets. Seasat, launched in 1978, extended coverage to 72° north and south latitude. However, it only lasted for 98 days. Geosat came next, with a coverage similar to that of Seasat, and successfully operated from 1985 to 1992. The ERS series began in 1991 and extended coverage to 81.5° north and south latitude.

Because the antenna size of these altimeters range from 1 to 2 m in diameter, they have a large beam footprint on the surface of the Earth. Altimeter data over ice sheet should be corrected to remove slope-induced errors. Further, measurements are adjusted at crossovers, where successive satellite paths intersect. ERS-1 altimeter data have been processed with this method. The resulting DEMs with a 10-km footprint covers the areas of the Antarctica to the north of 81.5° S. Further south, the hole was filled using an airborne-based data set. This data set is an important component of a recently created DEM of Antarctica, which gains improvement in a Geographic Information System (GIS) environment through integrating the best available topographic data from a variety of sources. The available Antarctica DEM serves as an input to ice sheet flow models, and helps determine the location of features such as grounding lines and correct geometric radiometric distortions inherent in SAR images.

Measurement of elevation change by space- or airborne altimeters offers a method of determining changes in ice volume and therefore mass balance. The distribution of crossover differences in an area tends to resolve regional changes in elevation. The technique has been used to estimate decadal elevation changes of ice sheets in south Greenland and East Antarctica. Considering the large spatial (−15 to +18 cm yr\(^{-1}\)) and temporal variations (\(\pm 15\) cm yr\(^{-1}\)) in the former case, the derived average growth rate of 1.5 \(\pm 0.5\) cm yr\(^{-1}\) is too small to determine if the Greenland ice sheet is undergoing a long-term change due to a warmer polar climate. In the latter case, inconsistency of the adjusted Seasat to Geosat vs Seasat to ERS-1 results was found. Both cases indicate the need for further improvements in satellite altimetry using laser techniques and more accurate satellite orbit tracking methods.

### 4.3 Use of Microwave Brightness to Estimate Surface Accumulation of Ice Sheets

Accurate estimation of the annual rate of net mass accumulation at the surface of the Antarctic and Greenland
ice sheets is a key element in global climate modeling. In addition to estimation of the accumulation rate by measurement of ice sheet surface elevation changes through altimetric techniques, the rate can also be estimated from passive microwave brightness temperatures.

The temperature at the surface of ice sheets in Antarctica and interior Greenland is always well below freezing point. For dry snow, the emissivity of a snowpack depends on the grain size, which in turn depends on accumulation rate. With time, snow grains metamorphose to ever larger grains until they eventually form pure ice. Hence low-accumulation regions have relatively older, and therefore relatively larger, grains nearer the surface than do high-accumulation regions. Based on radiative transfer theory, snowpack in low-accumulation regions ought to be more reflective at microwave wavelengths. According to energy conservation, such regions tend to be less absorptive at microwave wavelengths. Kirchhoff’s law further indicates that a less absorptive surface must be less emissive under thermodynamic equilibrium. Consequently, the snowpack in low-accumulation regions has lower emissivity than that in the high-accumulation regions of the ice sheet, as indicated by theoretical analysis and microwave measurements.\(^{(55,56)}\)

The microwave emissivity of snowpack is estimated by the mean annual passive microwave brightness temperature divided by the mean annual surface temperature, based on Nimbus-5 electronically scanning microwave radiometer (ESMR) and Nimbus-7 TIR data. Meanwhile, two coefficients are determined for each region or each ice sheet to fit best the field-measured accumulation rates with a theoretical-based hyperbolic function. Once the coefficients have been determined, the microwave emissivity and mean annual surface temperature are used to estimate the net mass balance. The method was used to derive accumulation values in Greenland and Antarctica. The results appears to be reliable for the areas of dry-snow facies. Vaughan et al.\(^{(57)}\) refined the method for Antarctica through improvements in basin delineation using automated techniques on an improved DEM, digital calculation of surface areas and basin-wide integrations and interpolation of sparse data using independent background field. Their results indicate that the total net surface mass balance for conterminous grounded ice sheet is \(1811\) Gton yr\(^{-1}\) and for the entire ice sheet including ice shelves and embedded ice rises \(2280\) Gton yr\(^{-1}\). The uncertainty is at least \(\pm5\%\).

4.4 Use of Synthetic Aperture Radar Backscatter and Interferometry to Track Glacier Ice Motion

SAR backscatter images have been used to track ice motion in glaciers and ice sheets. In essence, this technique is no different from the determination of ice motion using visible images using cross-correlation techniques.\(^{(58,59)}\) The cross-correlation technique using SAR backscatter has been applied to measure the surface ice velocities on Greenland ice sheet,\(^{(49)}\) Pine Island Glacier in West Antarctica\(^{(60)}\) and Malaspina Glacier in Alaska.\(^{(61)}\)

The surface ice flow in northeast Greenland was derived by computer-determined displacement of features in two images acquired 105 days apart.\(^{(49)}\) Results for the middle reach of Lakobshavns Isbrae show that the ice flow in this area is extremely rapid; the velocity is as high as \(2\) km yr\(^{-1}\). The accuracy of the velocity derived is about \(\pm80\) m yr\(^{-1}\) based on a one-pixel misregistration between the two images; this error is proportional to the inverse of the time interval.

Pine Island Glacier is one of the major ice streams draining West Antarctica. Lucchitta et al.\(^{(60)}\) calculated average velocities for both its grounded and floating parts by tracking crevasses and other patterns moving with ice on two sequential images acquired in February and December 1992 by ERS-1 SAR. Velocities in the fast-moving central parts of the glacier ranged from about \(1.3\) km yr\(^{-1}\) on the grounded part to \(2.6\) km yr\(^{-1}\) on the floating part. The velocity increases rapidly just below the grounding line. For the floating part, velocities are approximately \(0.3\) km yr\(^{-1}\) faster than previously established from Landsat images. The new observation suggests that the discharge is larger and, therefore, the mass balance less positive than previously thought.
